Chapter from the book *Type 1 Diabetes Complications*

Downloaded from: [http://www.intechopen.com/books/type-1-diabetes-complications](http://www.intechopen.com/books/type-1-diabetes-complications)
1. Introduction

Diabetes mellitus is a group of metabolic disorders of carbohydrate metabolism in which glucose is underutilized, producing hyperglycemia. The disease is classified into several categories. The revised classification, published in 1997 (ADA, 1997; The Expert Comitee on the Diagnosis and Classification of Diabetes mellitus, 2000), defines Type 1 diabetes mellitus (formerly known as the insulin-dependent diabetes mellitus or juvenile-onset diabetes mellitus) as a disorder caused by autoimmune destruction of pancreatic h-cells, rendering the pancreas unable to synthesize and secrete insulin. In 85–90% of cases, antibodies appear against pancreatic h-cells (ICA), acting as anti-insulin (IAA), or others such as GAD, IA-2 and IA-2h (Geiss et al 1997).

The latter complications of diabetes mellitus include both microvascular complications (predominantly retinopathy, nephropathy and neuropathy) and macrovascular complications, particularly stroke and coronary artery disease. Together, these make diabetes the seventh most common cause of death in the developed world (Geiss et al 1997).

The major microvascular complications, retinopathy and nephropathy, are the more important causes of blindness and end-stage renal disease in Europe. There are few similarities in the coexistence of DR and DN being both as microvascular disease and microscopically both have capillary basement membrane thickening. However, capillary closure is apparent in the retina and kidney after sufficient exposure to disease with duration. The pathophysiology of DN and DR are more or less similar, which commence with increase in vascular permeability. The selective increase in permeability to albumin in early DN is caused by loss of polarity across the glomerular basement membrane thickening, and the disease mechanism in the eye is probably a breakdown of tight junctions between cells. The onset of proteinuria and proliferative retinopathy are both related to previous poor glycemic control, duration of diabetes and hypertension.

The detection of retinopathy is easy (by the use of fundus periodical retinographies), but the diagnosis of the early stages of nephropathy needs microalbuminuria to be determined in
urinalysis. Microalbuminuria has prognostic significance; thus, in 80% of people with Type 1 diabetes mellitus and microalbuminuria, urinary albumin excretion increases at a rate of 10–20% per year, with the development of clinical proteinuria within 10–15 years. After the development of clinical grade proteinuria (>80%), patients go on to develop decreased glomerular filtration rate and, given enough time, end-stage renal disease (Geiss et al 1997). Several factors appear to influence susceptibility to the microvascular complications of diabetes mellitus, but our knowledge of the role and the importance of these genetic and environmental factors are still incomplete. The most powerful risk factor for microvascular complications was the duration of diabetes, but frequency of both retinopathy and nephropathy was impressively related to the level of plasma glucose at the time of examination. From the recent studies, it is evident that the presence of retinopathy itself may reveal patients at risk for nephropathy (Estacio et al, 1998; El Asrar et al, 2002; Rossing et al, 2002; Villar et al, 1999). In a cross sectional study, patients with DR were 5.68, 13.39 and 3.51 times as likely to have DN among type1 and type2 diabetic patients (El-Asrar et al, 2002). However, there is lack of evidence that determine the association of retinal-renal complications using the gold standard methods. The DR is characterized by microvascular abnormalities, proliferation of retinal vessels and increased retinal vascular permeability leading to the development of non-proliferative and proliferative DR, and macular edema (Williams et al 2004). The DN is a life threatening complication which predisposes to excess morbidity and mortality resulting from renal failure and cardiovascular disease (Ritz et al, 1999; Adler at al, 2003).

Our hypothesis was that the severity of DR correlates with the presence and severity of DN in people with type 1 diabetes. Studies in other populations documented a well-known association between advanced DR stages and overt nephropathy in type 1 diabetic patient (Looker et al, 2003; Gall et al, 1997). Similarly, our results provide further support to the close relationship between presence of DR and severity of DN in type1 diabetic patients.

It was reported that at least one fifth of the diabetic individuals are affected by multiple complications and the frequency increases with increasing age and duration of diabetes. In the study of WESDR, there was a strong correlation between DN and severity of DR in all age groups (Klein et al, 1984; Klein et al 1984).

In the present study we determine the epidemiological risk factors that influence the appearance of diabetic retinopathy, and overt nephropathy, in a seventeen -year follow-up of a population sample of 112 patients who did not have diabetic retinopathy or microalbuminuria at the beginning of the study.

2. Methods

2.1 Sample size and study population
Since 1987 a register has been kept of any new cases of type I diabetes mellitus in Catalonia (Spain). The incidence of new cases over that period has been 11.4 cases per 100000 inhabitants (13.2 cases in men and 9.6 cases in women) (Castell et al, 1999). Since 1990, there has been an ongoing registration of all diabetic patients (type I and 2) at St Joan Hospital, which is the only surgical ophthalmology centre in Reus (Spain), and having a dependent population of around 207,500 inhabitants. In 1999, there were 1495 patients with diabetes mellitus type I (Castell et al, 1999).
2.2 Design
The present study is prospective and was initiated in 1990 with 126 patients recruited with type I diabetes mellitus. The initial conditions included the absence of retinopathy and nephropathy (determined by the absence of microalbuminuria in three consecutive measures taken at one month intervals).

Two previous results were obtained at 5 and 10 years of the study (Romero-Aroca et al, 2000; Romero-Aroca et al, 2003). At the end of the study in 2007 only 112 patients were still being controlled (14 patients had dropped out during the follow up). At the end of the study (seventeen years of follow-up) the authors have determined the incidence of diabetic macular oedema and their risk factors, related to the appearance of renal overt nephropathy.

2.3 Diagnostic methods
Diabetic retinopathy was evaluated by retinal photographs through dilated pupils, of two 50º fields of each eye centred firstly at the temporal to the macula and secondly at the nasal to the papilla (Aldington et al, 1995). The results were then classified into four groups (Wilkinson et al 2003):

- Mild non proliferative
- Moderate non proliferative
- Severe non proliferative
- Proliferative

Macular edema was diagnosed under stereoscopic viewing of the macula with a slit lamp and Goldmann fundus contact lens, and was considered present if we found:

- retinal thickening involving or within 500 μm of the centre of the macula
- hard exudates at or within 500 μm of the centre of the macula, if associated with thickening of adjacent retina (but no hard exudates remaining after retinal thickening disappeared)
- a zone or zones of retinal thickening, one disc area or larger in size, any part of which is within 1 disc diameter of the centre of the macula.

The clinical classification used was the international clinical diabetic retinopathy disease severity scale, proposed by the American Academy of Ophthalmology in 2002 (Wilkinson et al 2003). In all patients with diabetic macular oedema, a fluorescein angiography was obtained, centred on macular region to determine the leakage in that area. The fluorescein angiographic findings were categorized into three types:

- focal leakage type, which was predominantly well-defined focal areas of leakage from microaneurysm or localized dilated capillaries;
- diffuse leakage type, predominantly widespread and ill-defined leakage involving the whole circumference of the fovea;
- cystoid leakage type, predominantly diffuse leakage but with pooling of dye in the cystic spaces of the macula in the late phase.

Since 2000, all patients with diabetic macular oedema have been given an optical coherence tomography (OCT), repeated every 4 months as a control test. Optical coherence tomography was performed with a OCT model TOPCON TRC NW 7SF. The retinal map algorithm uses measurements along 6 radial lines, 6 mm in length, to produce a circular plot in which the foveal zone is the central circular zone of 1.00 mm in diameter. Macular edema measured by OCT was defined as a retinal thickening of more than 216 microns, and was classified as follows, using the Otani et al patterns amplified by the two tractional forms.
described later (Otani et al, 1999): Sponge-like retinal thickness, defined as increased retinal thickness with reduced intra retinal reflectivity and expanded areas of lower reflectivity; cystoid macular oedema, characterized by the intra retinal cystoid spaces at the macular area; serous retinal detachment was thought to be present if the posterior surface of the retina was elevated above the outer border of the highly reflective band, regarded as the signal generated mainly by the retinal pigment epithelium. Only patients with a visible separation between the layer of photoreceptors and the pigment epithelium, was classified as serous detachment; if we observed the photoreceptor layer adjacent to pigment epithelium, we classified the case as cystoid macular oedema.

2.4 Inclusion criteria
Patients with type I diabetes mellitus (insulin dependent or young-onset diabetes mellitus)

2.5 Exclusion criteria
Presence of diabetic retinopathy at the beginning of study, presence of diabetic nephropathy at the beginning of study, presence of microalbuminuria at the beginning of study, patients with LADA diabetes (latent autoimmune adult diabetes), patients with type 2 diabetes mellitus (not insulin-dependent or older-onset diabetes mellitus), patients with type 2 diabetes mellitus appeared before 30 years of age (MODY diabetes mellitus)

2.6 Definition of variables
Visual acuity in each eye was measured on the Snellen chart and recorded as a decimal value, with best refraction for distance. All data manipulations were performed on visual acuities expressed in log MAR form. The legal blind subject was defined as corrected visual acuity less than or equal to 0.1 in the better eye; reduced visual acuity as less than or equal to 0.4 and greater than 0.1 in the better eye.

The epidemiological risk factors included in the study were:

- Gender and current age.
- Duration of diabetes mellitus, classified in the statistical study in two groups: below 20 years of duration and equal to or more than 20 years duration.
- Type of diabetic retinopathy classified into two groups: first with a diabetic retinopathy lower than severe pattern, and the second with patients with severe or proliferative pattern, patients who need scattered photocoagulation were classified in this second group.
- Arterial hypertension, which indicates a systolic measurement above or equal to 140 mm Hg and the diastolic measurement above or equal to 90 mm Hg, or when the patient is taking anti-hypertensive medications.
- Levels of glycated haemoglobin (HbA1c) as recommended by the American Diabetes Association (ADA, 1997) as the major component of HbA1c (accounting for 80% of HbA1c), was measured every 3 months. The control of glycaemia was considered in concordance with the European Diabetes Policy Group, into two groups of patients i.e. over or under 7.0% (European Diabetes Policy Group, 1999). The value included in the statistical analysis was the mean of all values obtained over the 15 years.
- Presence of microalbuminuria, defined as increased albumin excretion (30-300 mg of albumin/24 h or 20-200 µg/min of creatinine) on two of three tests repeated at intervals of 3-6 months as well as exclusion of conditions that invalidate the test (Geiss et al,
1997). The test was performed annually. After microalbuminuria was diagnosed, repeated testing was made within a period of 3-4 months.

- Presence of diabetic nephropathy, defined as clinical albuminuria or overt nephropathy by the American Diabetes Association, corresponding to protein excretion >300 mg/24h (>200 µg/min or >300 µg/mg of albumin: creatinine ratio). Measurement of creatinine clearance as an index of glomerular filtration rate was performed on the same urine collection (Geiss et al, 1997).
- Patients were classified as having macro vascular disease if one or more of the following were present: symptoms of angina pectoris, history of myocardial infarction, coronary artery by pass grafting, percutaneous tranluminal coronary angioplasty, symptoms of or operation for intermittent claudication, history of amputation, transient ischemic attack, stroke.
- Levels of triglycerides and fractions of cholesterol (HDL-cholesterol and LDL-cholesterol). In the statistical analysis, we classified the patient into normal or higher values, according to the ADA categories as patients with high risk if LDL-cholesterol 3.35 mmol/L (130 mg/dl), HDL-cholesterol 0.90 mmol/L for men and >1.15 mmol/L for women (35 mg/dL for men and 45 mg/dL for women), and triglycerides 1.5 mmol/dl (400 mg/dl), (Expert Panel on Detection, Evaluation, And Treatment of high Blood Cholesterol in Adults, 2001).

2.7 Statistical methods

All statistical analyses were carried out using the SPSS software package (version 18.0), results are expressed as mean±standard error, a P-value of less than 0.05 was considered to indicate statistical significance.

Differences between those included in analyses were examined using the two sample Student T-tests or one-way ANOVA, for continuous or quantitative data, as visual acuity or current age. For the qualitative or categorical data we used the Chi-square test in the univariate phase of study, with determination of Odds ratio for each variable.

The Kruskal-Wallis test and the least significant difference test using ranks for multiple comparisons were carried out to evaluate the correlation between best-corrected visual acuity an OCT findings.

In the multivariate phase of analysis the relationship of diabetic retinopathy, microalbuminuria and overt nephropathy, to various demographic and other risk factors were examined using logistic regression analysis; the full model was built including gender and age a priori.

3. Results

Demographic variables of the patients

Gender: 54 patients were men (48.2%) and 58 were women (51.8%)
The mean of age was 39.94 ± 10.53 years old (24 - 61 years), the mean of diabetes mellitus type I duration was 23.42 ± 7.57 years (12 – 45 years). The arterial hypertension was present in 44 patients (39.3%).
The means of the different quantitative data were:
- Glycosylated haemoglobin A1c: 7.69% ± 1.24 (4.50% – 11.40%)
- LDL-Cholesterol: 3.50 ± 0.57 mmol/l (3.00 – 4.00)
- HDL-Cholesterol: 1.12 ± 0.42 mmol/l (0.70 – 2.02)
- Triglycerides: 1.47 ± 0.76 mmol/l (0.90 – 3.00)

Visual acuity study

Mean visual acuity after 17 years was 0.77 ± 0.34 (0.02 – 1) in the Snellen chart test; and +0.37 ± +0.72 (+1.7 - +0) in the Log MAR test.

Low vision (defined as vision in the best eye >0.1 and < 0.4 in the Snellen chart) was detected in 13 patients (11.6%) and blindness (AV < 0.1 in Snellen chart) in 14 patients (12.5%).

**Incidence of diabetic retinopathy (Table 1)**

After 17 years there were 62 patients (55.4%) with different types of diabetic retinopathy. The Rate of progression was 8.30 person-year.

- Mild diabetic retinopathy in 31 patients (27.7%)
- Moderate diabetic retinopathy in 7 patients (6.3%)
- Severe diabetic retinopathy in 5 patients (4.5%)
- Proliferative diabetic retinopathy in 18 patients (16.1%)

There were 23 patients (20.5%) with diabetic macular edema after 17 years, the Rate of progression was 3.08 person-year. The mild or moderate form of diabetic macular edema was present in 13 patients (11.6%) and the severe form of macular edema in 10 patients (8.9%).

In the 62 patients with diabetic retinopathy 17 (27.42%) developed overt nephropathy, with a rate of progression 4.11 person-year. In patients with proliferative form of diabetic retinopathy (23 patients) 11 developed microalbuminuria (47.82%), the rate of progression was 7.17 person-year.

**Statistical study of diabetic retinopathy**

Univariate study with the application of chi squared test (Table 1).

The factors significant in the appearance of diabetic retinopathy were as follows: duration of diabetic retinopathy p<0.001, presence of arterial hypertension p<0.001, levels of glycated haemoglobin (HbA1c) > 7.5% p<0.001, high levels of LDL-cholesterol p<0.001, high levels of tryglicerides p=0.003 and presence of overt nephropathy p= 0.001.

Logistic regression of diabetic retinopathy (Table 2).

The followings factors studied were significant in the appearance of diabetic retinopathy: Duration of diabetes mellitus more than 20 years p< 0.001, presence of arterial hypertension p<0.001, high levels of HbA1c p< 0.001, high levels of tryglicerides p=0.004, high levels of LDL-Cholesterol p= 0.002, and overt nephropathy p=0.021.

**Statistical study of diabetic nephropathy**

Univariate analysis with the application of chi squared test(Table 1).

The factors significant in the apparition of overt nephropathy were: presence of arterial hypertension p=0.001, high levels of HbA1c p<0.001, high levels of LDL-Cholesterol p=0.010, high levels of triglycerides p=0.003, and presence of diabetic retinopathy p=0.021. When we introduced the presence of proliferative diabetic retinopathy against the presence of any retinopathy, the chi squared test had a result of p<0.001, and for proliferative diabetic retinopathy p< 0.001.
Logistic regression of diabetic nephropathy (Table 2).

The significant factors were: the presence of arterial hypertension $p<0.001$, and high levels of HbA$_1c$ $p<0.001$, high levels of LDL-Cholesterol $p=0.002$, high levels of triglycerides $p=0.009$. Also the presence of diabetic retinopathy was significant $p=0.021$. When we introduced the presence of proliferative diabetic retinopathy against the presence of any retinopathy, the chi squared test had a result of $p<0.001$.

Table 2. Fisher’s classification coefficient.

Statistical application of discriminate analysis

At the end of the study we may observe that four groups of patients had been formed:

- those without any form of microangiopathy (overt nephropathy or retinopathy) 45 patients (group A).
- those with only retinopathy (45 patients) (group B).
- those with only overt nephropathy (5 patients) (group C).
- those with both overt nephropathy and retinopathy (17 patients) (group D).

In this case we needed to apply a discriminate analysis to evaluate the risk factors for the different groups. Applying Fisher’s coefficient indicated that (Table 2):

- for group B the risk factors were: duration of diabetes mellitus (4.679), high levels of HbA1c (2.250) and high levels of LDL-Cholesterol (2.268).
- for the group C only the high levels of HbA1c (7.250) were highly correlated.
- for the group D the significant factors were: high levels of HbA1c (6.471), presence of arterial hypertension (2.657), high levels of triglycerides (2.810) and duration of diabetes mellitus (2.269).

4. Discussion

The diabetic retinopathy (DR) and diabetic nephropathy (DN) are the two major complications of diabetes mellitus. The proliferative diabetic retinopathy and proteinuria secondary to DN are both late complications of diabetic overt nephropathy, these usually occur 10 to 15 years after the onset of type 1 DM, and are strongly associated with each other. The epidemiology of diabetic overt nephropathy and retinopathy in type 1 DM are different, thus for diabetic overt nephropathy increases its prevalence since 10% at ten year duration of diabetes mellitus, achieving the highest value after 40 years with a 40% of diabetic patients with nephropathy, since this point the curve levels off, and only a minority of patients develop clinically significant renal abnormalities, and patients who survive 35 years of type 1 DM without developing DN are at extremely low risk of doing so in the future. Against this curve the diabetic retinopathy succeed in a different form in type 1 diabetic patients, thus the diabetic retinopathy is rare before 10 years DM duration, and...
increases the prevalence, since this point to a levels upper 80% after 20 years diabetes duration, without a decreases after these 20 years of duration, as we observed in our study. The incidence of DR was 55.4% , and was lower than in other studies such as Klein et al 1998 (Klein et al, 1998), but this may be because the sample studied did not present diabetic retinopathy at the beginning and patient controls were stricter than in the rest of the patients with diabetes mellitus type I (controls every 3 months), we could concluded that the mean level of HbA1c was 7.69% ± 1.24 (4.50% – 11.40%) is better than the achieved by WESDR (Klein et al, 1998). The diabetic macular edema appeared in 20.5% of patients, which was more similar to the findings in the Klein study at 14 years (26%). In the present study the incidence of diabetic macular edema is higher than the proliferative form of diabetic retinopathy in type I diabetes mellitus patients, as was observed in other studies.

With regard to nephropathy diabetes accounting for more than 19.6% of all cases of DN. The DN presents initially as intermittent microalbuminuria that progresses to persistent microalbuminuria, and is accompanied by a decline in the glomerular filtration rate. These dates were in agreement with other studies published in our country on renal failure in diabetes mellitus type I patients Smatjes et al (Esmatjes et al, 1998) found an incidence of 44.5% with some form of renal failure at 20 years in type I diabetes mellitus.

The relationship between DN and DR was well described, thus the Wisconsin Epidemiologic Study of Diabetic Retinopathy (Klein et al, 1993) associated the presence of gross-proteinuria at baseline examination with a 96% increase in the risk of progression to proliferative retinopathy. Also in the Steno study (Kofoed-Enevoldsen et al, 1987), people with type I diabetes mellitus and gross-proteinuria at baseline had an increase risk of progression to proliferative retinopathy (12% annually) compared to those without proteinuria (1%-2% annually).

At the end of our study we can see that four groups of patients had formed: those without overt nephropathy or diabetic retinopathy (45 patients), patients with only overt nephropathy (5 patients), those with only diabetic retinopathy (45 patients), and those with overt nephropathy and diabetic retinopathy (17 patients). The statistical test used for examining these data was a discriminate test, which allowed us to identify the risk factors that influence any of these groups.

In the group of patients with only DR the duration of diabetes mellitus was the more important risk factor and for the group with Dr and DN the most important risk factor is the high levels of HbA1c.

We may assume then, that for the development of only retinal lesions in diabetes mellitus, the duration of the disease is the most important followed by and in a second level of importance the levels of HbA1c and arterial hypertension; and for the development of renal and retinal lesion simultaneously poor control of glycaemia measured by levels of HbA1c were more important than the duration of diabetes mellitus.

Two broader groups of patients can be assumed to have been formed in this study, the first being those patients who developed only diabetic retinopathy, and the second those with both diabetic retinopathy and renal lesion (overt nephropathy). This conclusion is consistent with previous studies as that of Lövestam-Adrian in 1998 (Lövestam-Adrian, et al, 1998), in which after a 10-year follow-up of a population of 24 patients, with proliferative diabetic retinopathy at the beginning of the study, only two developed microalbuminuria, That study concluded that there are, at least partly, different pathogenic mechanisms behind diabetic retinopathy and overt nephropathy.
5. Conclusion

Despite there being a poor relationship between overt nephropathy and diabetic retinopathy \((p=0.021 \text{ in the present study})\), the presence of overt nephropathy correlated well with severe forms of diabetic retinopathy (as proliferative DR \(p<0.001 \text{ in the present study})\); and in addition, at the end of study two broad group of patients had been configured, the first those who developed only diabetic retinopathy, and the second with diabetic retinopathy and renal lesion (overt nephropathy). For the first group with only DR, duration of diabetes mellitus is the most important risk factor, and for the second group (patients with DR and DN) the levels of HbA1c and blood pressure are the most important.

6. References

Looker HC, Krakoff J, Knowler WC, Bennett PH, Klein R & Hanson RL (2003). Longitudinal studies of incidence and progression of diabetic retinopathy assessed by retinal photography in Pima Indians. Diabetes Care;26:320-326. ISSN 0149-5992

This book is a compilation of reviews about the complication of Type 1 Diabetes. T1D is a classic autoimmune disease. Genetic factors are clearly determinant but cannot explain the rapid, even overwhelming expanse of this disease. Understanding etiology and pathogenesis of this disease is essential. The complications associated with T1D cover a range of clinical obstacles. A number of experts in the field have covered a range of topics for consideration that are applicable to researcher and clinician alike. This book provides apt descriptions of cutting edge technologies and applications in the ever going search for treatments and cure for diabetes.
