Heparin-Induced Thrombocytopenia

Kazuo Nakamura
Nihon Pharmaceutical University
Japan

1. Introduction

Heparin is an effective anti-coagulant for the prevention of venous thromboembolism and for the treatment of venous thrombosis and pulmonary embolism (Girolami et al., 2003; Hirsh et al., 2004; Shantsila et al., 2009). It is often used for patients with unstable angina and acute myocardial infarction, and for patients who have undergone vascular surgery (Battistelli et al., 2010). The administration of heparin frequently induces a reduction in platelet counts. This phenomenon is called heparin-induced thrombocytopenia (HIT) and be classified as either type I or II. To avoid confusion between the syndromes, “HIT type I” has been changed to “non-immune heparin associated thrombocytopenia”, and “HIT type II” is simply called “HIT”.

The origin of non-immune heparin associated thrombocytopenia is not yet completely understood, though it is thought to be caused by heparin-induced platelet clumping (Fabris et al., 1983; Chong & Ismail, 1989). Thrombocytopenia of this type is mild (platelet count, $>100 \times 10^9$ cells/L), not progressive, nor associated with bleeding or thrombosis (Salzman et al., 1980), and is independent of any immune reaction (Chong et al., 1993a; Burgess & Chong, 1997; Shantsila et al., 2009). It is characterized by a transitory, slight and asymptomatic reduction in platelet count, occurring during the first 1-2 days of heparin administration. This phenomenon gradually resolves without interruption of heparin administration, and platelet counts gradually rises to pre-treatment levels within a few days without special treatment. Non-immune heparin associated thrombocytopenia may be related to the direct binding of heparin to platelet membranes (Salzman et al., 1980; Fabris et al., 1983; Chong & Ismail, 1989).

In this view, the term HIT refers only to HIT type II. HIT is associated with a heparin-related immune reaction. It is a prothrombotic disease initiated by administration of heparin, and is related to antibody-mediated platelet activation causing thrombin generation and thrombotic complications. Thrombocytopenia is common in hospitalized patients, occurring in up to 58% of critically ill individuals, and can be caused by a variety of factors (Strauss et al., 2002). HIT, which is associated with significant morbidity and mortality if unrecognized, can be regarded as a very severe side effect of a drug, (Chong, 1992; Aster, 1995; Chong, 2003). Unfortunately, HIT often remains unrecognized, undiagnosed, and untreated, a problem that can be rectified with increased awareness and a high degree of suspicion for HIT. Current treatment recommendations are based on recent advances in research on the pathophysiology and the natural history of HIT (Jang & Hursting, 2005). HIT should be considered a clinicopathologic syndrome (Warkentin et al., 1998; Warkentin, 2002, 2003).
since its diagnosis is based on both clinical criteria, such as thrombocytopenia and thrombosis, and laboratory data, such as platelet count dynamics and the detection of HIT antibodies (Shantsila et al., 2009).

However, HIT is often difficult to diagnose because of the following phenomena: 1) nonimmune heparin-associated thrombocytopenia occurs in 10-30% of patients receiving heparin (Blank et al., 2002); 2) HIT antibody seroconversion is observed in the absence of thrombocytopenia or other clinical sequelae; and 3) enzyme-linked immunosorbent assay (ELISA) detects both clinically irrelevant (non-pathogenic) and clinically relevant (pathogenic) antibodies (Shantsila et al., 2009). Seroconversion of anti-HIT antibody without thrombocytopenia or other clinical sequelae is not considered HIT, whereas a diagnosis of HIT can be made when anti-HIT antibody formation is accompanied by an otherwise unexplained platelet count fall, or by skin lesions at heparin injection sites or acute systemic reactions after intravenous injection of heparin (Bartholomew et al., 2005). Furthermore, HIT formation may also be related to the occurrence of venous limb gangrene occurring in HIT patients treated with oral anticoagulants (Warkentin, 1996a). A mnemonic device, the “4 Ts” of HIT, has been developed to remember the salient clinical features of HIT, thus facilitating patient assessment and HIT diagnosis (Warkentin & Heddle, 2003): the degree of thrombocytopenia, the timing of the platelet fall, the presence of thrombosis or other sequelae, and other potential causes of thrombocytopenia (Lillo-Le Louët et al., 2004; Denys et al., 2008; Gruel et al., 2008).

Despite the utility of this memory device, severe morbidity and mortality in HIT patients persists because of lack of awareness accompanied by a delayed diagnosis. Thus, we have developed the following chapter to provide an overview of HIT, focusing particularly on the epidemiology, pathophysiology, diagnosis, laboratory evaluation, and treatment.

2. Overview of HIT

HIT type II, namely, HIT, is immune-mediated and associated with a risk of thrombosis. It develops in approximately 5-10% of patients treated with heparin and is characterized by a significant reduction in platelets (levels fall by 30% or more), generally after the fifth day of therapy (Warkentin et al., 1998; Warkentin, 2002). Although, this phenomenon is usually resolved by therapy within 5-15 days, some cases may require months of treatment (Chong, 1992; Warkentin et al., 1998; Warkentin, 2002).

Platelet count monitoring is recommended for heparin-treated patients in whom the risk of HIT is high (e.g., postoperative patients) or intermediate (e.g., medical or obstetric patients receiving a prophylactic dose of heparin or postoperative patients receiving antithrombotic prophylaxis) (Chong et al., 1993a; Jang & Hurusting, 2005). Shantsila et al. (2009) have recommended measurement of platelet counts before, and 24 h after, initiation of heparin therapy in patients who have received heparin within the past 100 days. Platelet counts should also be performed every 2-3 days in intermediate-risk patients, every other day in high-risk patients, and immediately in patients with systemic, cardiorespiratory, or neurologic symptoms that occur within 30 min after an intravenous injection of heparin.

HIT should be suspected when thrombocytopenia (<15-20 × 10^9 cells/L, or a >50% decrease in platelet count) occurs during heparin administration, typically 5-14 days after initiation of heparin administration (Warkentin & Kelton, 2001a); however, very severe
thrombocytopenia (platelet count <15-20 × 10^9 cells/L) is generally not due to HIT. Routine platelet count monitoring for HIT may be appropriate in at least some clinical situations, and it may be reasonable to stratify the intensity of need for platelet count monitoring in relation to the risk of HIT.

Although it is difficult to predict which heparin-exposed patients will develop HIT, one consistent factor is a property of heparin preparation. HIT antibodies occur at higher levels in patients given bovine unfractionated heparin (UFH) than in those treated with porcine UFH or low molecular weight heparin (LMWH) (Green et al., 1984; Bailey et al., 1986; Monreal et al., 1989; Rao et al., 1989; Warkentin et al., 1995; Warkentin et al., 2003a; Lee & Warkentin, 2004; Denys et al., 2008; Gruel et al., 2008).

HIT antibody formation is also influenced by the medical circumstances in which heparin is administered. For example, approximately 20% of heparin-exposed patients develop HIT antibodies after orthopedic surgery, while as many as 70% develop antibodies after receiving a cardiopulmonary bypass (CPB) (Amiral et al., 1996a). However, it can be difficult to compare results across studies because of differences in duration and route of anticoagulant administration, as well as patient group composition (Lee et al., 2004).

3. Epidemiology

There is a need for studies on HIT incidence. The work that has been done is sufficient, and they have so many differences that it is difficult to compare results across studies in order to uncover broader trends. Most HIT studies are retrospective, and differ with respect to patient characteristics, type of heparin preparation, duration of therapy, definition of thrombocytopenia, and laboratory tests used for confirm thrombocytopenia diagnosis (Schmitt & Adelman, 1993; Magnani, 1993; Chong, 2003). Despite these problems, it is possible to draw some general conclusions about HIT epidemiology.

There are 3 characteristic profiles in the timing of the onset of thrombocytopenia. Approximately 70% of HIT patients are classified as “typical-onset HIT”. In these patients, platelet counts begin to decrease (seroconversion and initial platelet count fall) within 5-10 days after beginning heparin treatment (Warkentin & Kelton, 2001a). Approximately 25-30% of HIT patients are classified as having “Rapid-onset HIT”, which occurs when platelet counts fall abruptly within 24 h of starting heparin therapy (Warkentin & Kelton, 2001a; Lubenow et al., 2002). “Rapid-onset HIT” is strongly associated with recent heparin exposure, usually within the preceding 100 days (Warkentin & Kelton, 2001a; Lubenow et al., 2002). Because of the previous exposure, patients already have circulating HIT antibodies, which cause platelet counts to fall quickly once heparin is re-administered. The last category of HIT, affecting approximately 3-5% of HIT patients, is “delayed-onset HIT” in which the onset of thrombocytopenia begins several days after completion of heparin treatment (Warkentin & Kelton, 2001b; Rice et al., 2002; Warkentin & Bernstein, 2003; Warkentin, 2004a). This type of syndrome is often clinically severe, as it is associated with high-titer, platelet-activating HIT antibodies that do not require ongoing heparin administration to exert their pathogenic effect (Rice et al., 2002). Furthermore, this type may occur in patients exposed to minimal amounts of heparin, although it has also been observed in patients exposed to large amounts of heparin during coronary artery bypass grafting (Rice et al., 2002; Jackson et al., 2006). Rarely, patients who received intravenous heparin develop acute inflammatory or cardiorespiratory symptoms and signs within 30 min (Warkentin, 2007).
HIT severity is mainly determined by the extent of thrombotic complications (Girolami et al., 2003). Many HIT patients develop thrombosis after receiving as an antithrombotic prophylaxis (Warkentin, 1996a; Wallis et al., 1999). The thrombotic event is frequently a worsening of pre-existing thrombosis in heparin-treated HIT patients, and this worsening of thrombosis may cause a new thromboembolic complication (Magnani, 1993; Warkentin & Kelton, 1990, 1996; Nands et al., 1997); this has been observed in approximately 20% of cases (Wakentin, 2004a). Development of a new thrombus or extension of an existing thrombus during treatment with prophylactic or therapeutic UFH or LMWH should always raise a suspicion of HIT (Shantsila et al., 2009). The first event to be associated with HIT was arterial thrombosis, which seems to be more frequent in patients with cardiovascular disease (Nands et al., 1997); venous complications may be common in patients undergoing postsurgical prophylaxis (Rhodes et al., 1973; Magnani, 1993; Warkentin & Kelton, 1996). In most cases, arterial complications manifest as thromboses of the large vessels, leading to gangrene and limb amputation, stroke, myocardial infarction, and cardiac thrombosis (Warkentin & Kelton, 1990; Boshkov et al., 1993; Fondu, 1995; Chong, 1995).

Approximately 10-20% of patients who develop HIT while receiving subcutaneous injections of heparin experience skin lesions, ranging from painful erythematous plaques to skin necrosis, at the injection sites (Warkentin, 2004a; Chong, 1995). Skin lesions have been observed in patients without thrombocytopenia but with circulating HIT antibodies (Warkentin, 1996b). Occasionally, HIT associated with intravenous heparin injection also manifests as an acute systemic reaction developing within 5-30 min after heparin administration (Ansell et al., 1986; Popov et al., 1997; Warkentin, 2004a).

Estimates of HIT prevalence among heparin-treated patients differ depending on heparin type. Fabris et al. (2000) found that laboratory-confirmed HIT occurs in approximately 2% of patients receiving UFH. Among patients given therapeutic doses of bovine UFH, HIT has been observed in approximately 5% of patients. This is a much higher rate than that observed in patients given procine UFH (1%). Prophylactic doses of porcine heparin have been reported to cause HIT in <1% of patients (Warkentin & Kelton, 1990). However, risk of HIT is relatively low in medical and obstetric patients receiving LMWH (Fabris et al., 2000). For instance, Warkentin (2004a) reorted that HIT was observed in 2.7% of patients treated with subcutaneous UFH injection, but in no patients receiving LMWH; further, thrombotic complications were more frequent in the former group (88.9%) than in the latter (17.8%). Both the bovine/procine UFH and the LMWH data were collected from medical patients receiving LMWH or UFH as “flushes”, e.g., oncology patients with indwelling catheters (Mayo et al., 1990; Kadidal et al., 1999). A randomized controlled trial that compared use of procine UFH with LMWH after hip replacement surgery found that HIT was significantly less common among patients who received the latter treatment (Lee & Warkentin, 2004; Warkentin, 2004a).

4. Pathophysiology

Francis and colleagues have reported that HIT antibody formation in cardiac surgery patients who received procine UFH was significantly lower than those with bovine UFH (Francis et al., 2003). The IgG fraction of HIT patients serum has been found to cause in vitro platelet aggregation in the presence of therapeutic amounts of heparin (Rhodes et al., 1973), indicating that HIT has an immunologic etiology (Amiral et al., 1998; Warkentin et al., 2000).
Green et al. (1978) reported that immunoglobulin-heparin complexes form only in the presence of platelets (Green et al., 1978), and several platelet proteins have been proposed as the receptors of heparin-dependent antibodies (Lynch & Howe, 1985). Multiple studies have found that the pro-aggregating effect of heparin depends on the degree of sulfation and the molecular weight of the heparin (Geinacher et al., 1992; Geinacher et al., 1993; Kelton et al., 1994) and is mediated by the release of platelet alpha-granules (Gruel et al., 1993), which contain platelet factor 4 (PF4), a small, positively charged molecule produced by megakaryocytes. Although its biological function is unknown, it has been identified as the main co-factor of heparin (Amiral et al., 1992; Gentilini et al., 1999); it also binds to endothelial-surface glycosaminoglycans, e.g., heparin sulfate (Visentin et al., 1994; Cines et al., 2007). Normal blood levels of PF4 are very low, as it is only released into circulation following weak platelet activation. However, PF4 levels may be high in specific clinical circumstances, such as prosthetic hip or cardiac surgery, which are associated with platelet activation (Greinacher et al., 1994a). When heparin binds with PF4, it undergoes a conformational change and becomes immunogenic, leading to the generation of anti-heparin/PF4 antibodies, namely, HIT antibodies (Suh et al., 1998; Ziporen et al., 1998). The PF4/heparin ratio is important for the constitution of the multimolecular antigenic complex, and the optimal PF4/heparin ratio has been reported to range from 4-6:1 (Kelton et al., 1994; Visentin et al., 1994; Amiral et al., 1995; Cines et al., 2007). The immunogenicity of heparin-PF4 conjugates may form the biological basis for differences in immunogenicity between bovine and porcine sources of heparin: Bovine lung heparin has longer polysaccharide chains and a higher degree of sulfation, which could increase reactivity with PF4 (Boshkov et al., 1993).

HIT antibodies activate platelets and stimulate an immunomediated endothelial lesion, followed by the appearance of thrombocytopenia and/or thrombosis (Fondu, 1995; Greinacher, 1995; Warkentin et al., 1998; Cines et al., 2007). Platelet activation is primarily caused by binding between the immunocomplex and FcγRIIa (CD32) receptors (Adelman et al., 1989; Anderson et al., 1995; Baglin, 2001), leading to degranulation and the release of pro-coagulant substances (e.g., serotonin, histamine, and adenosine diphosphate), thromboxane biosynthesis, an influx of Ca²⁺, and the generation of highly pro-thrombotic phospholipid microparticles (Chong et al., 1981; Chong et al., 1989a; Warkentin & Kelton, 2001a). The immunocomplex can bind to Fc receptors on the surfaces of monocytes, neutrophils, and endothelial cells, and the binding of the immunocomplex to so many types of cells can contribute to the profound thrombin generation seen in patients with HIT. Thrombin generation can be enhanced by HIT activation of monocytes and endothelial cell tissue factor on the surface of monocytes and endothelial cells (Visentin et al., 1994; Warkentin, 1999; Newman & Chong, 2000; Pouplard et al., 2001; Arepally & Mayer, 2001). These thrombotic processes may lead to a hypercoagulable state, thus increasing the risk of severe and extensive thromboembolic complications in many patients. Additional activation of platelets by thrombin and other released agonists results in a further increase in the numbers of FcγRIIa receptors on the platelet surface, facilitating even more platelet activation (Chong et al., 1993b; Anderson et al., 1995). However, some reports have indicated that platelet activation can be blocked by the FcγRIIa receptor-specific monoclonal antibody (IV.3) (Kelton et al., 1988; Visentin et al., 1994).

While IgG-class HIT antibody can be detected in most HIT patients, IgA and IgM HIT antibodies can be found in only a small portion of patients (Suh et al., 1997; Amiral et al.,
Given that IgA and IgM antibodies do not activate platelets in the presence of heparin in vitro, and that they are unable to bind FcγRIIa, their presence in HIT patients could simply be coincidental, though IgM and IgA are not able to bind to FcγRIIa (Amiral et al., 1996a; Amiral et al., 1996b; Amiral et al., 1996c; Blank et al., 1997). These data suggest that platelet activation occurs independently of the IgG FcγRIIa receptor. After heparin administration is interrupted, the HIT antibody gradually disappears; laboratory tests for HIT antibodies are usually “negative” or “weakly positive” at 100 days (Shantsila et al., 2009). For HIT to develop at this point, the HIT antibody would need to form again (Lubenow et al., 2002; Rice et al., 2002). Harris et al. (2008) have reported an association between the PLA2 polymorphism of glycoprotein IIIa and the risk of thrombosis in patients with HIT antibodies.

5. Diagnosis of HIT

The diagnosis of HIT should be based both on clinical criteria, such as the presence of thrombocytopenia and thrombosis, and laboratory data, such as platelet count dynamics and detection of HIT antibodies. However, it may be difficult to establish a general diagnostic protocol, given the lack of a readily accessible standard laboratory test and the frequent detection of elevated anti-HIT antibody levels in heparin-treated patients that display no clinical features of the disease (Arepally & Ortel, 2006).

In the majority of patients with HIT, thrombocytopenia is defined as an otherwise unexplained >50% drop in the platelet count (Warkentin et al., 2008a); thrombocytopenia is generally of moderate severity, and median platelet count is approximately 50-60 x 10⁹ platelets/L (Jackson et al., 2006). In HIT patients, platelet counts are generally < 20 x 10⁹ platelets/L. Clinical presentation of HIT in patients with profound thrombocytopenia can be rapidly progressive and include the development of disseminated intravascular coagulation and microvascular thrombotic complications (Ortel, 2009). Patients are likely to suffer from HIT when their platelet counts drop to less than 50% of normal levels and when they present with thrombosis or skin lesions at heparin injection sites (Jackson et al., 2006).

Generally, platelet count decreases and/or thrombotic events begin 5–10 days after the initiation of heparin therapy in heparin-hypersensitive individuals, and platelet count in thrombocytopenic patients may not return to initiation levels until several days later (Warkentin & Kelton, 2001a). In patients who have undergone operation, the expected pattern would show a return of normal platelet count immediately after surgery, followed by an unexpected drop (Warkentin, 2003). Persistent thrombocytopenia following cardiac bypass surgery is usually not a result of HIT, but instead may stem from other causes, such as postoperative complications. However, postoperative thrombocytopenia lasting for >5 days without an apparent alternative cause may be the result of HIT (Lillo-Le et al., 2004).

Several diagnostic algorithms have been developed to provide a more systematic approach to the diagnosis of HIT. Patients can be assigned an HIT score using the “4 Ts,” an assessment protocol and memory device focused on the salient clinical features of HIT: degree of Thrombocytopenia (maximum points for a platelet count fall of >50% or a nadir of 20–100 x 10⁹/L), the Timing of the fall in platelet count (maximum points for an onset of 5–10 days after initiation of heparin treatment or within 1 day if there has been recent heparin exposure), the presence of Thrombosis or other sequelae (maximum points for new thrombosis, skin lesions, or acute systemic reactions), and oTher causes of...
thrombocytopenia excluded (maximum points for no other cause event) (Warkentin, 2003, Warkentin et al., 2003b, Bryant et al., 2008). The “4 Ts” is useful for following the recommendation of Warkentin and Heddle, who suggest the employment of a clinical decision-making model to establish a pretest probability for HIT in patients who receive UFH or LMWH (Warkentin & Heddle, 2003). A diagnostic score for HIT after cardiopulmonary bypass surgery has also been proposed (Lillo-Le et al., 2004). Other studies have demonstrated the usefulness of combining the 4Ts score with laboratory testing when diagnosing HIT (Lillo-Le et al., 2004; Denys et al., 2008; Gruel et al., 2008); laboratory tests can also be used independently for confirming a clinical diagnosis.

5.1 Laboratory testing

Laboratory testing is necessary to confirm the diagnosis of HIT, and is most helpful in these patients clinically assessed to be at intermediate high clinical risk of HIT (Arepally & Ortel, 2006). Patients who have undergone cardiopulmonary bypass surgery frequently have elevated antiheparin/PF4 antibody levels; among these individuals, testing should not be used to “screen” patients for HIT or evaluate patients assessed to have a low pre-test probability for HIT (Warkentin et al., 2008a). Although a lot of laboratory tests are available for detection of heparin-PF4 antibody, these tests have several advantages and disadvantages. Blood sampling for the detection of HIT antibodies was performed in patients with clinically suspected HIT on days 5 to 14 following the initiation of heparin therapy (Warkentin et al., 2008a). Although HIT antibodies are detectable in the blood for several weeks after heparin administration, discontinuation of heparin administration, samples should be collected as soon as possible because antibody levels can decrease quite rapidly.

The first test developed for diagnosing HIT was the platelet aggregation test, which uses citrated platelet-rich plasma (PRP) and standard platelet aggregometry (Warkentin, 2004b). The platelet aggregation test is able to provide results quickly (Kelton et al, 1988), although results of this test is more influenced by heparin concentrations and donor platelet variability compared to those of 14C-serotonin release assay (SRA) (Warkentin & Kelton, 1990; Chong, 1992, 1995). Accordingly, to increase sensitivity and specificity, test conditions need to be optimized—instance, by washed platelets (Chong et al., 1993a; Greinacher et al., 1994a; Pouplard et al., 1999a). Washed platelet activation assays, such as the platelet SRA, (Sheridan et al., 1986; Warkentin et al., 1992; Warkentin, 2001; Price E et al., 2007), and the heparin-induced platelet activation test (Greinacher et al., 1991; Greinacher et al., 1994a) are used by a few reference laboratories. In these assays, it is necessary to use of apyrase in a wash step for maintenance of platelet reactivity to HIT antibodies, and to resuspend in a calcium- and magnesium-containing buffer (Polgár et al., 1998; Warkentin, 2001). The major limitation of this method is its technically demanding nature (Warkentin, 2000), which limits its use to a few reference laboratories. In most clinical laboratories, immunological tests such as ELISA are used because they are easy to perform, have a rapid turnaround time, and are highly sensitive (Price et al., 2007). There are 2 PF4-dependent antigen assays that are commercially available for detecting HIT antibodies (Amirál et al., 1992; Collins et al., 1997; Warkentin, 2000; Warkentin et al., 2001): the Asserachrom (Stago, Asnières, France), which detects antibodies that react with PF4-heparin complexes, and the GTI-PF4 (GTI, Brookfield, WI, USA), which detects antibodies that react with PF4 bound to polyvinyl sulfonate.
Prospective studies have shown that, among HIT antibody classes, only HIT-IgG antibodies have very high sensitivity for diagnosing clinical HIT (Warkentin et al., 2000; Lindhoff-Last et al., 2001). Detection of PF4-heparin antibodies is performed as followed. Unbound material is removed, and a chromogen is added to label the bound conjugate, producing a yellow color, read at 405 nm. The amount of yellow produced at the end point, as indicated by the optical density (OD), is proportional to the amount of antibody present. A positive result is reported if OD reading is 0.400 or more. Higher ELISA OD results have been shown to significant correlation of the serotonin release assay results and an increased risk for thrombosis in patients with HIT (Warkentin et al., 2008b). Furthermore, the ELISA results are most useful when combined with a clinical scoring system (Janatpour et al., 2007). Zwicker et al (2004) have reported that higher ELISA OD measurements correlated significantly with thrombosis, and patients with isolated HIT (HIT in the absence of thrombosis) and an OD level of 1.0 or more had a 6-fold increased risk of thrombosis compared with patients who had OD levels between 0.4 and 0.99 (Zwicker et al, 2004). The sensitivity of the ELISA for PF4-heparin antibodies is greater than functional assays (Greinacher et al., 1994b; Amiral et al., 1995; Pouplard et al., 1999b), though a “positive” result may not denote the same magnitude of thrombotic risk.

5.2 Laboratory data from 2 potential HIT patients

We examined 2 patients who experienced thrombocytopenia after being given UFH during percutaneous transluminal coronary angioplasty (PTCA) and cardiac surgery. For both individuals, we tested for HIT by measuring platelet aggregability and quantifying levels of both anti-heparin-PF4 complex antibody (anti-HIT antibody) and thrombin-antithrombin III complex (TAT). Platelet aggregation in response to 0.2 μg/mL collagen was measured using Born’s turbidimetric methods (Born GVR, 1962), and quantified by light transmission, as previously reported (Toyohira et al., 1995; Kariyazono et al., 1997; Nakamura et al., 1999); platelet aggregation activity was evaluated as percent maximum aggregation (MA). First samples were prepared by incubating the PRP of suspected HIT patients with UFH (0.2 IU/mL), and second samples were prepared by separately adding plasma from the 2 patients to the PRP of healthy volunteers at a ratio of 1:1, then adding UFH (0.2 IU/mL). We then used a commercial ELISA kit (GTI Diagnostics, Waukesha, WI, NJ, USA) to measure anti-heparin antibodies in these samples.

As shown in Figure 1, platelet aggregation was much higher in the first set of sample than in the first control sample (without UFH); in other words, heparin had a strong positive effect on aggregation. As a result, MA of second sample was 68% (Figure 2), and showed strong aggregation. The ELISA results indicated significantly higher OD values for the 2 potential HIT patients than in the healthy volunteers. Furthermore, remarkably high levels of circulating TAT and TNF-alpha were found in the plasma of the suspected HIT patients. Our laboratory data indicate the likelihood that anti-HIT antibodies were present in the plasma of both patients. Furthermore, these data demonstrate the marked acceleration of blood coagulation in these patients, suggesting an increased risk of thrombosis.

These findings support previous reports that many HIT patients are hypercoagulable and have greatly elevated levels of TAT (Warkentin et al., 1997; Greinacher et al., 2000); furthermore, this helps explain the strong relationship between HIT and venous or arterial thrombosis (Warkentin & Kelton, 2001a).
Fig. 1. Platelet aggregation was stimulated by 0.2 μg/mL collagen. In case A’s PRP incubated without UFH (first control sample) (C). In healthy volunteer’s PRP incubated with UFH (second control sample) (B). In case A’s PRP incubated with UFH (A).

Fig. 2. Anti-heparin antibody was detected by turbidimetric method. Collagen (0.2 μg/mL) was used as agonist. In case A’s PRP incubated without UFH (first control sample) (C). In healthy volunteer’s PRP was mixed with case A’s plasma following incubation without UFH (third control sample) (B). In healthy volunteer’s PRP was mixed with case A’s plasma following incubation with UFH (A).
Given these findings, we propose a model for the pathophysiological mechanism of HIT (Figures 3 and 4). This model helps explain observations that the hypercoagulable state, coupled with endothelial cell dysfunction due to injury from heparin antibody, activated platelets, leukocytes, platelet microparticles, atherosclerosis or medical intervention, can lead to arterial thrombosis (Walenga et al., 2000). Furthermore, the model is supported by the report that anti-HIT antibodies bind to and directly activate microvascular endothelial cells, whereas binding to and activating macrovascular endothelial cells requires pre-activation by platelets or TNF-alpha (Walenga et al., 2004).

![Diagram of HIT mechanism](https://www.intechopen.com)

**Fig. 3.** Pathophysiological mechanism of HIT (1). Stage 1; binding of heparin to PF4 induces the formation of a neoepitope. Stage 2; an immune response against the PF4/heparin complex induces antibody formation. Stage 3; the complex of PF4/heparin and specific antibody associates with platelets via binding of the antibody Fc part to the platelet immunoglobulin receptor FcγRIIa (CD32), representing the major stage in platelet activation in HIT. Stage 4; activated platelets shed procoagulant microparticles which enhance thrombin generation.
Fig. 4. Pathophysiological mechanism of HIT (2). Stage 5; binding of released PF4 to heparan sulfate of endothelial cell induces the formation of PF4/glycosaminoglycans complex on the surface of endothelial cell. Stage 6; PF4/glycosaminoglycans complex antibody binds to PF4/glycosaminoglycans complex on the surface of endothelial cell, and activates endothelial cell. Stage 7; activation of endothelial cells lead to the release of activated factor X. Stage 8; thrombin generation induces thrombus formation.

6. Management of HIT

All heparins must be avoided when treating patients suspected to have HIT; even exposure to very low amounts of heparin through heparin-coated catheters and heparin flushes used to maintain intravenous lines may trigger HIT (Laster et al., 1989). Likewise, preparations of LMWH can induce severe HIT, though they do so less frequently than UFH (Warkentin et al., 2003a; Warkentin & Greinacher, 2003; Walenga et al., 2004). Further, the cross-reactivity rate between heparin and LMWH is so high that LMWH is not recommended for the treatment of HIT patients (Chong, 2003; Warkentin et al., 2008a). Alternative anticoagulant therapy must be initiated immediately, both for HIT patients diagnosed with thrombocytopenia alone or with thromboembolism (Warkentin & Greinacher, 2004). In patients in whom treatment was delayed until an HIT diagnosis could be confirmed by laboratory tests, the incidence of new thrombosis was approximately 10-fold higher than in individuals treated promptly with a direct thrombin inhibitor (Greinacher et al., 2000).

Marked decreases of platelet counts in HIT patients require anticoagulation with an effective antithrombotic drug that does not cross-react in vivo with the circulating anti-heparin/PF4
There are currently 3 thrombin inhibitors available for patients with HIT: lepirudin, argatroban, and bivalirudin, all of which directly bind and inactivate thrombin. Prospective cohort studies have been performed to investigate the efficacy and major bleeding endpoints for lepirudin (Greinacher et al., 1999a; Greinacher et al., 1999b; Lubenow et al., 2004; Lubenow et al., 2005) and argatroban (Lewis et al., 2001; Lewis et al., 2003) in patients with HIT complicated by thrombosis. When respective historical control data were taken into consideration, composite end point risk rates and new thrombosis risk rates were 0.48 and 0.28 for lepirudin, respectively, and 0.75 and 0.45 for argatroban, respectively. The corresponding absolute event rates were 19.2% (lepirudin) and 42.3% (argatroban) for the composite end point, and 7.0% (lepirudin) and 15.5% (argatroban) for new thrombosis. Patients who received lepirudin were less likely to require amputation than those who were given argatroban. Fatal bleeding after treatment with lepirudin has been found to range from 1.2% of patients (in a prospective study) to 3.9% of patients (in a retrospective observational study) (Lubenow et al., 2005; Tardy et al., 2006). Danaparoid and fondaparinux may also be used to manage HIT (Warkentin et al., 2008a). When abrupt decreases in platelet count (to <10 × 10^9 cl/L) are observed in patients who underwent angioplasty and were treated with a combination of heparin and glycoprotein IIb/IIIa antagonist, the recommended antagonist is always glycoprotein IIb/IIIa (Shantsila et al., 2009).

6.1 Lepirudin

Lepirudin, a recombinant form of hirudin, is a direct, specific, and irreversible inhibitor of thrombin that is administered via intravenous injection (Greinacher & Lubenow, 2001). The biggest drawback of Lepirudin is that it must be accompanied by the strict laboratory monitoring: activated partial thromboplastin time (aPTT) monitoring should be performed at 4-h intervals until it is clear that patients have reached a steady state within the normal range of values (Warkentin et al., 2008b). Moreover, patients should be informed that they have received lepirudin, since fatal anaphylactic reactions have been reported in patients re-exposed to lepirudin during a second round of intravenous treatment (Greinacher et al., 2003). Although similar bleeding rates have been observed in lepirudin-treated patients and historical control subjects, this drug has been found to significantly reduce the combined end point of death, limb amputation, and new thromboembolic complications in patients with HIT associated thrombosis (Greinacher et al., 1999a; Greinacher et al., 1999b).

6.2 Argatroban

Argatroban is a synthetic L-arginine-derived direct thrombin inhibitor that reversibly binds to the thrombin active site. Argatroban is administered by intravenous injection, with dose adjustment to maintain aPTT at 1.5-3.0 times the baseline value (Gosselin et al., 2004). It has been reported that, in HIT patients without thrombosis, treatment with argatroban produces a significant reduction in the composite end point, such as all-cause death, all-cause limb amputation, and new thrombosis at 37 days (Lewis et al., 2001; Lewis et al., 2003). In HIT patients who underwent lower extremity revascularization, the composite end point of deaths, urgent revascularization, and limb amputations developed in 25% of patients treated with argatroban, and 6% of patients had major bleeding episodes (Baron et al., 2008). Restoration of platelet counts is universally observed within 6–7 days of the initiation of
argatroban therapy (Bartholomew et al., 2007). Some precautions are required when argatroban infusion is overlapped by warfarin anticoagulant therapy, although argatroban causes a further substantial increase in the international normalized ratio (INR). In addition, careful thought should be given to the participation of direct thrombin inhibitor to the patient’s INR.

### 6.3 Danaparoid

Danaparoid is approved as an alternative anticoagulant for HIT in many countries. Danaparoid, a heparinoid with predominantly anti-Xa activity and some anti-Ⅱa activity, is a mixture of three glycosaminoglycans such as heparin sulfate, dermatan sulfate, and chondroitin sulfate. Danaparoid presents its anticoagulant effect by catalyzing the inactivation of factor Xa in the presence of antithrombin, and has a unique property of specific suppression of HIT antibody-induced platelet activation that is not observed with other drugs used for HIT treatment (Chong et al., 1989b). Tardy-Poncet et al. reported that major bleeding episodes in those patients treated with danaparoid were significantly fewer compared with those treated with lepirudin (Tardy-Poncet et al., 1999). Among the drugs used for the treatment of HIT, danaparoid is the only drug whose efficacy and safety have been confirmed by a prospective randomized controlled study (Chong et al., 2001).

### 6.4 Bivalirudin

Bivalirudin, which is not approved as an HIT treatment, is a 20-amino acid polypeptide with sequence homology to hirudin. Campbell et al. (2000) reported 94% procedural success in a series of 17 percutaneous coronary intervention patients who were given bivalirudin as a treatment for HIT (Campbell et al., 2000). In the Anticoagulant Therapy with Bivalirudin to Assist in the Performance of Percutaneous Coronary Intervention in Patients with HIT (or ATBAT) multicenter open-label trial (Mahaffey et al., 2003), clinical percutaneous coronary intervention success, defined as the absence of death, emergency bypass surgery, or Q-wave infarction, was achieved in 96% of patients treated with bivalirudin; further, patients displayed a low rate of bleeding. Cumulatively, these results indicate that bivalirudin therapy is safe and effective during percutaneous coronary intervention.

### 6.5 Fondaparinux

Fondaparinux, a synthetic pentasaccharide with potent indirect anti-Xa inhibitor properties, is used only a limited number of patients with HIT. The generation of HIT-related antigen depends on the polysaccharide chain length (Amiral et al., 1995). Because patients have a very low risk of developing HIT while receiving fondaparinux (Warkentin et al., 2005), platelet count monitoring is not needed during administration of this drug. Despite these advantages, fondaparinux cannot be recommended for in the treatment of HIT until there are more data demonstrating its efficacy and safety (Rota et al., 2008; Lobo et al., 2008).

### 7. Conclusion

Heparin is one of the most widely used and valuable anticoagulants for the treatment and prophylaxis of thrombotic complications. However, HIT is not only a common but also a
serious complication of heparin therapy with a high rate of morbidity and mortality. Its prompt clinical and laboratory recognition is necessary to stop heparin administration immediately and start an alternative anticoagulant. HIT antibody test results must be interpreted in the appropriate context of the available clinical information. Furthermore, additional diagnostic information is available as a result of considering the magnitude of a given positive test result. The diagnosis of HIT should be clearly recorded in the patient’s notes and marked as a serious allergy.

8. References

Hematology encompasses the physiology and pathology of blood and of the blood-forming organs. In common with other areas of medicine, the pace of change in hematology has been breathtaking over recent years. There are now many treatment options available to the modern hematologist and, happily, a greatly improved outlook for the vast majority of patients with blood disorders and malignancies. Improvements in the clinic reflect, and in many respects are driven by, advances in our scientific understanding of hematological processes under both normal and disease conditions. Hematology - Science and Practice consists of a selection of essays which aim to inform both specialist and non-specialist readers about some of the latest advances in hematology, in both laboratory and clinic.
