11

Wealth of Flora and Vegetation in the La Campana-Peñuelas Biosphere Reserve, Valparaiso Region, Chile

Enrique Hauenstein
Catholic University of Temuco, Faculty of Natural Resources, Temuco Chile

1. Introduction

Chile has a National System for State-Protected Wilderness Areas (Sistema Nacional de Áreas Silvestres Protegidas del Estado – SNASPE), which consists of three categories: National Parks (PN), National Reserves (RN) and Natural Monuments (MN). It presently contains 95 units, covering in total 19% of the country's territory. SNASPE has become a fundamental pillar not only for safeguarding an important part of Chile's natural heritage but also for protecting and valuing our cultural heritage, particularly where it is integrated in the areas which make up this system (Oltremari, 2002). By 1985, UNESCO had designated 7 Biosphere Reserves in Chile: Lauca, Fray Jorge, Juan Fernández, La Campana-Peñuelas, Araucarias, Laguna San Rafael and Torres del Paine. To these were later added Cabo de Hornos [Cape Horn], Bosques Templados Lluviosos de los Andes [Wet Temperate Andean Forests], and recently Laguna del Laja-Nevados de Chillán.

The Valparaiso Region contains La Campana National Park, declared a Biosphere Reserve in February of 1985 jointly with Lago Peñuelas National Reserve due to their high biological and ecosystem diversity, representative of the mediterranean environments characteristic of this region (Weber, 1986; CONAF, 1992, 2008; Elórtegui & Moreira, 2002). In 1834, during his stay in Chile, the great naturalist Charles Darwin climbed to the peak of La Campana where he was amazed by the presence of forests of palm trees (*Jubaea chilensis*), and especially by recording a specimen at 1,350 m above sea level (Elórtegui & Moreira, 2002).

The central zone of Chile, also called the mesomorphic or mediterranean zone, extends approximately from 32° to 37° S (Pisano, 1956). It has a mediterranean climate, which Koeppen (1931, 1948) classifies as a "warm-temperate climate with sufficient humidity", in the subdivision "winter rains and prolonged dry season", characterised by regular periods of rain in winter and a strongly marked dry season which may extend from six to eight months. This corresponds to other mediterranean zones around the world such as in California and southern Europe in the Northern Hemisphere, and Australia and southern Africa in the Southern Hemisphere (Grau 1992; Arroyo et al., 1995). The climatic conditions mean that the vegetation in these regions has specially adapted characteristics, such as the presence of sclerophyllous leaves, lignotubers and a great capacity for water-use efficiency (Money & Kumerow, 1971; Araya & Avila, 1981; Avila et al., 1981). According to

Marticorena et al. (1995), the central zone of Chile is a focus where endemic species are concentrated, with great wealth and diversity of flora. Mittermeier et al. (1998) indicate the presence of 1,800 species of endemic plants for this area, leading it to be considered as one of the world's 25 hotspots, requiring priority protection (WWF & IUCN, 1997; Myers et al., 2000).

In this context, flora and vegetation studies are essential basic elements for developing proposals for the conservation and management of species and ecosystems, or defining priority areas (Cavieres et al., 2001; Teillier et al., 2005). The object of the present study is to contribute to knowledge of the flora and vegetation of the La Campana-Peñuelas Biosphere Reserve.

2. Methods and results

2.1 Study area

This Biosphere Reserve includes La Campana National Park (32°55' to 33°01'S; 71°01' to 71°09'W) and Lago Peñuelas National Reserve (33°07' to 33°13'S; 71°24' to 71°34'W). It is important to indicate that by means of offer of the National Forest Corporation of Chile, the year 2008 extended his surface in near 14 times, going on from 17,095 to 238,216 ha (CONAF, 2008). The altitude ranges from ± 350 to ± 2,222 masl, and the highest peaks are "El Roble" (2,222 masl) and "La Campana" (1,920 masl). Some sectors of RN Lago Peñuelas contain plantations of exotic species (*Pinus radiata* D. Don and *Eucalyptus globulus* Labill.). Another part corresponds to Peñuelas lake, a reservoir covering 1,600 ha which supplies water to the cities of Valparaiso and Viña del Mar, and forms a wetland which is important for migratory,

occasional or resident birds; more than 125 species of water, land and shore birds have been recorded in the lake (Strang, 1983) (figure 1, photos 1, 2, 3). The climate of the area is temperate-mediterranean, with sufficient humidity, winter rains and a prolonged dry season. The average annual temperature is 13.5ºC; the average maximum is 17.1ºC and the average minimum is 9.4ºC; the temperature occasionally falls to 0ºC, with frosts between May and September. Precipitation is seasonal (656 mm/year), from the end of May to August, with a markedly dry summer of six to eight months from October to March (Di Castri & Hajek, 1976; Luebert & Pliscoff, 2006).

2.2 Methodology

The study of the flora and vegetation of the Reserve was carried out by field activities and bibliographic review. Field trips were done in February and November 2001, with intensive collection and 27 phytosociological surveys in nine sampling stations in the Peñuelas National Reserve. The area of each inventory was 4 m² for herbaceous vegetation, 25 m² for shrubs and 100 m² for forest species, within areas greater than the minimum area (Steubing et al., 2002). Aquatic and marsh vegetation were also included on the shores of Peñuelas lake. The phytosociological tables were processed according to the methodology proposed by Braun-Blanquet (1964, 1979), as explained in Ramírez & Westermeier (1976). The bibliographic review was based principally on the following works: Looser (1927, 1944), Rundel & Weisser (1975), Rodríguez (1979, 1982), ICSA (1980), Villaseñor (1980, 1986), Villaseñor & Serey (1980-1981), Balduzzi et al. (1981, 1982), Rodríguez & Calderón (1982), CONAF (1986, 1994), Zöllner et al. (1995), Elórtegui & Moreira (2002), Novoa et al. (2006), CONAF (2008) and Hauenstein et al. (2009).

The identification, nomenclature and geographical origin of each species was based on Muñoz (1966), Navas (1973, 1976, 1979), Hoffmann (1978, 1991), Marticorena & Quezada (1985), Matthei (1995), Hoffmann et al. (1998) and Marticorena & Rodríguez (1995, 2001, 2003, 2005). The International Plant Names Index (IPNI 2011) was used to update the scientific names and abbreviations. Life forms were determined according to the scheme proposed by Ellenberg & Mueller-Dombois (1966) and the state of conservation of the species was determined considering the proposals of Benoit (1989), updated by a meeting of experts in September 1997 (Baeza et al., 1998; Belmonte et al., 1998; Ravenna et al., 1998), and de Novoa et al. (2006) for the Orchidaceae. The degree of human disturbance of the site was determined on the basis of the proposal of Hauenstein et al. (1988) and the evaluation scale of González (2000), which consider phytogeographic origin (the ratio between native and introduced species), and life forms (Raunkiaer's biological forms) as measurements of this form of disturbance. The result was an inventory of the flora in the study area (table 2), containing all the above elements.

The vegetation units were determined using the maps produced by CONAF & CONAMA (1999) and specific cartography provided by CONAF (National Forest Corporation), Valparaiso Region. The definition and nomenclature of the vegetation units followed the proposal of Gajardo (1995). The vegetation units identified in the map for study were subsequently verified on the ground.

2.3 Results

Flora. The vascular flora recorded (table 2) included 420 species distributed as: 12 Pteridophytes (3.0%), 3 Gymnosperms (1.0%), 290 Dicotyledons (69.0%) and 115 Monocotyledons (27.0%) (figure 2). The phytogeographic origin (figure 3) indicates that 49.0% of the species (207 sp.) are native, 28.0% (118 sp.) endemic and 23.0% (95 sp.) introduced. The biological spectrum (life-forms; figure 4) was represented by 122 hemicryptophytes (29.0%), 112 therophytes (26.4%) corresponding to annual and biannual plants, 72 cryptophytes (17.1%) including hydrophytes and geophytes, 52 nanophanerophytes (shrubs) (12.4%), 38 phanerophytes (trees) (9.0%), 14 vines (3.3%), 5 chamaephytes (low shrubs) (1.4%), 4 parasites (1.0%) and only one epiphyte (0.2%).

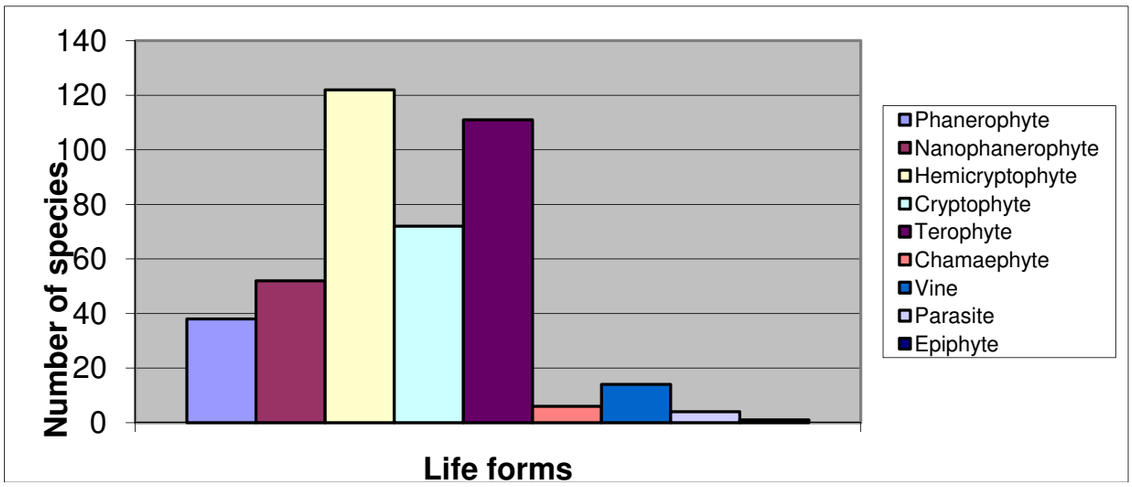

Fig. 4. Biological spectrum (life forms) of the flora in La Campana-Peñuelas Biosphere Reserve, Chile.

The state of conservation of the species (table 1), considering the total mentioned for the area, shows that the majority present no problems, with 18 species (4.5%) being identified as suffering from conservation problems. Of these, two are in the "Endangered" category, *Beilschmiedia miersii* (belloto del norte) and *Calydorea xiphioides* (tahay); 14 in the "Vulnerable" category, mainly species of bulbs (geophytes) such as *Herbertia lahue, Leucocoryne ixioides, L. violacescens* and *Phycella bicolor*; two in the "Rare" category, *Alstroemeria garaventae* and *A. zoellneri*; and just one species in the "Insufficiently known" category, *Blechnum cordatum*, of which a single specimen was recorded in the El Abrevadero sector.

Vegetation. The vegetation in the Reserve includes the following woody communities: sclerophyllous forest, hygrophilous forest, deciduous forest, thorny scrub and mixed sclerophyllous scrub. The herbaceous communities include: dry grassland, wet grassland, reed beds, sedge beds and the aquatic plant community. These communities are characterised as:

1. Peumo and boldo sclerophyllous forest. This is a woody formation typical of the region. This community corresponds to *Peumo-Cryptocaryetum albae* (Oberdorfer, 1960). Variants can be found with sclerophyllous scrub species (*Retanilla trinervia, Gochnatia foliolosa*), and one with Chilean palm tree (*Jubaea chilensis*). The average cover of the arboreal stratum is 70%, shrubs 35% and herbaceous 25%. The principal arboreal species are: *Cryptocarya alba*, *Peumus boldus, Persea lingue* and *Dasyphyllum excelsum*; shrubs are dominated by: *Retanilla trinervia, Schinus latifolia* and *Chusquea cumingii*,; creepers and lianas included: *Proustia pyrifolia, Lardizabala funaria* and *Cissus striata*; herbaceous vegetation comprised mainly: *Blechnum hastatum*, *Alonsoa meridionalis, Conyza floribunda* and *Anagallis arvensis.* The altitude ranges of this community is from 350 to 1,000 masl (Elórtegui & Moreira, 2002; Hauenstein et al., 2009).
2. Quillay and litre sclerophyllous forest. A more strongly xerophytic community than the first category described above, with cover between 40 and 90%. The principal arboreal species are: *Cryptocarya alba*, *Quillaja saponaria* and *Lithrea caustica*; shrubs: *Retanilla trinervia, Schinus latifolia, Colliguaja odorifera*, *Podanthus mitiqui* and *Escallonia pulverulenta;* and herbaceous species include: *Adiantum chilense, Solenomelus*

pedunculatus, Vulpia myuros, Alonsoa meridionalis, Conyza floribunda and *Anagallis arvensis*. The altitude range is from 500 to 1,050 masl. There is also a variant with *Jubaea chilensis*, in which *Aristeguietia salvia* and *Acacia caven* are also present (Elórtegui & Moreira, 2002; Hauenstein et al., 2009).

Table 1. Vascular plants with conservation problems of the La Campana-Peñuelas Biosphere Reserve (EC= condition of conservation, P= threatened, R= rare, V= vulnerable, IC= insufficiently known).

3. Temo and pitra hydrophilous laurifolious forest. Includes small remnants of forest associated with permanent watercourses and springs, present in the Vega del Alamo sector of RN Peñuelas. These are composed of hygrophilous species such as *Drimys winteri*, *Myrceugenia obtusa*, *Blepharocalyx cruckshanksii* and *Luma chequen*, and some creepers like *Lardizabala biternata* and *Cissus striata*, and correspond to the *Blepharocalyo-Myrceugenietum exsuccae* association (hualve or swamp forest) of myrtaceous plants in the central southern zone of Chile (Ramírez *et al*. 1996). These forests are included in the *Wintero-Nothofagetea* phytosociological class defined by Oberdorfer (1960). Other woody species present in this community were: *Maytenus boaria* and *Escallonia revoluta*, together with some creepers such as *Cissus striata* and *Lardizabala biternata*. The herbaceous stratum is scarce, probably due to the closed canopy, which hinders the penetration of

light; where present it is represented by *Uncinia trichocarpa* and ferns like *Blechnum hastatum* and *B. cordatum*. This community is found at 270 masl (Hauenstein et al., 2009).

4. Belloto hygrophilous laurifolious forest. This community is characterised by an arboreal stratum dominated by *Beilschmiedia miersii, Cryptocarya alba* and *Dasyphyllum excelsum*; there is an abundant shrub stratum dominated by *Azara celastrina, Chusquea cumingii, Adenopeltis serrata* and an abundance of creepers such as *Proustia pyrifolia, Lardizabala funaria* and *Bomarea salsilla*. It is found in low-lying areas, up to 500 masl (Elórtegui & Moreira, 2002).
5. Canelo hygrophilous laurifolious forest. The arboreal stratum, dominated by *Drimys winteri*; an abundant shrub stratum, with *Otholobium glandulosum, Escallonia myrtoidea, Maytenus boaria* and occasionally *Salix humboldtiana*; and in the herbaceous stratum, *Equisetum bogotense*. In altered sectors by human activities, cover may be diminished to as little as 30%. It is found at between 500 and 1,300 masl (Elórtegui & Moreira, 2002).
6. Deciduous roble forest. This community is characterised by a well differentiated arboreal stratum with *Nothofagus macrocarpa* and *Lomatia hirsuta*; a shrub stratum with *Azara petiolaris, Ribes punctatum, Schinus montanus, Berberis actinacantha* and *Aristotelia chilensis*; and an herbaceous stratum with, *Adiantum sulphureum, Loasa tricolor, Oxalis laxa* and *Alstroemeria zoellneri,* respectively. The cover is from 70 to 100% and it is found between 1,100 and 1,500 masl. At altitudes above 1,500 masl, a clear diminution may be seen in the tree and shrub cover, constituting a variant with other species such as *Schizanthus hookeri, Valeriana lepidota* and *Senecio anthemidiphyllus* (Elórtegui & Moreira, 2002) (photo 4).

Photo 4. *Nothofagus macrocarpa* forest in the sector of the Hill the Oak.

7. Espino thorny scrub. The dominant species in the community are espino (*Acacia caven* = *Vachellia caven*) and maitén (*Maytenus boaria*), with average cover of 50% and 10% respectively. It is characterised by the presence of a rich herbaceous stratum, especially *Agrostis capillaris, Leontodon saxatilis, Avena barbata, Bromus hordeaceus, Briza minor, B. maxima* and *Rhodophiala advena*, with clear predominance of forage graminids. This community is found around Peñuelas lake (Hauenstein et al., 2009) (photo 5).
8. Trevo thorny scrub. A little developed shrub community dominated by *Retanilla trinervia*, accompanied by shrub forms of *Lithrea caustica* and *Quillaja saponaria,* and by *Cuscuta chilensis*, an abundant, parasitic, herbaceous species. Average cover is above 70% and the community is found between 400 and 1,000 masl. It forms a variant with abundant presence of *Jubaea chilensis*, but only in the Ocoa sector (Elórtegui & Moreira, 2002).

Photo 5. *Acacia caven* steppe (hawthorn) in sectors near to the Peñuelas lake.

9. Chagual and quisco thorny scrub. An open community of succulents, with a shrub stratum of less than 4 m height, very diverse, with *Puya berteroana, Echinopsis chiloensis, Adesmia arborea, Aristeguietia salvia, Podanthus mitiqui, Retanilla trinervia* and occasionally *Puya chilensis*; the herbaceous stratum is poor, with *Helenium aromaticum, Vulpia myuros* and *Madia sativa*. Cover is very variable, between 10 and 80%, but generally not more than 40%. It is found at between 450 and 1,100 masl. It can also form a variant with abundant presence of *Jubaea chilensis*, but only in the Ocoa sector, with other species *Baccharis paniculata* and *Tristerix corymbosus* present (Elórtegui & Moreira, 2002) (photo 6).

Photo 6. *Jubaea chilensis* in the sector of Ocoa's Palms.

10. Chagualillo thorny scrub. A low, open shrub community, with two well differentiated strata: higher, with shrubs and succulents of 1-3 m in height, and lower, < 1 m. The higher stratum is dominated by *Puya coerulea, Eryngium paniculatum, Colliguaya odorifera, Retanilla ephedra* and *Calceolaria polifolia*; the lower by *Eriosyce curvispina, Tweedia birostrata, Gamochaeta americana, Senecio farinifer* and *Chorizanthe virgata*. Cover varies between 20 and 60%, and the altitude is above 1,100 masl. A variant may also be formed with presence of *Jubaea chilensis*, with very low cover, the individuals of Chilean palm tree being small and widely dispersed. These communities are found in certain high sectors of Cajón Grande, El Roble and Ocoa, and have cover $\pm$ 40% (Elórtegui & Moreira, 2002).
11. Mira and maicillo thorny scrub. A community with sparse distribution representing situations of sclerophyllous forest with severe disturbance in difficult environments for

plant life. The dominant species in the shrub stratum are *Gochnatia foliolosa, Baccharis rhomboidalis, B. linearis, Satureja gilliesii, Escallonia pulverulenta, Ageratina glechonophylla* and *Haplopappus velutinus*; in the herbaceous stratum, *Alstroemeria angustifolia, Solenomelus pedunculatus, Triptilion spinosum, Acaena pinnatifida* and *Azorella spinosa*. The community presents covers of 30 and 50%, at altitudes between 1,000 and 1,300 masl. It can also form a variant with *Jubaea chilensis*, with very low cover, between 1,000 and 1,200 masl. The differential character of this unit is given by the presence of *Vulpia myuros* and *Baccharis paniculata*, indicating a high level of degradation (Elórtegui & Moreira, 2002).

12. Mixed sclerophyllous scrub. This community is a mixture of species from the acacia steppe with sclerophyllous forest elements, such as *Quillaja saponaria, Schinus latifolia,* and *Cryptocarya alba*, together with shrub species, such as *Schinus polygama, Baccharis linearis, Berberis actinacantha, Eryngium paniculatum* and *Satureja gilliesii*. It may be characterised as open scrub of espino and romerillo (*Baccharis linearis*). The dominant woody species are *Acacia caven* with nearly 20% cover and *B. linearis* with 10%; these were followed by *Maytenus boaria*, *Quillaja saponaria* and *Schinus latifolia*; lower canopy comprises *Peumus boldus*, *Lithrea caustica*, *Escallonia pulverulenta* and the creeper *Muehlenbeckia hastulata*. The herbaceous stratum, with average cover 90%, was represented by the species *Agrostis capillaris*, *Avena barbata*, *Poa annua, Festuca sp*., *Bromus hordeaceus, Briza minor* and *Leontodon saxatilis* (Hauenstein et al., 2009).
13. Low altitude neneo scrub. A low, open community of dwarf shrubs (chamaephytes), principally *Mulinum spinosum, Chuquiraga oppositifolia, Viviania marifolia, Haplopappus ochagavianus, Ephedra chilensis* and a herbaceous stratum formed by *Phacelia secunda* and *Calceolaria campanae*. The cover is 10 to 40%; it is found on rocky substrates with variable exposure and gradient, above 1,750 masl, present only at the summits of La Campana and El Roble (Elórtegui & Moreira, 2002).
14. Dry grassland. The principal floral components of these grasslands were *Phyla canescens, Bromus hordeaceus, Agrostis capillaris, Hypochaeris radicata, Gamochaeta coarctata, Leontodon saxatilis, Rumex acetosella* and *Avena barbata*. They correspond to the *Bromo-Lolietum* community (Oberdorfer, 1960), and are found in the north-east sector of Peñuelas lake, at around 360 masl (Hauenstein et al., 2009).

15-16. Wet grasslands. There are two types. Apart from some of the species of the previous community, the first is distinguished by *Mentha pulegium* and reeds (*Juncus acutus*, *J. cyperoides*, *J. pallescens*), and corresponds to reedy wet grassland (*Juncetum acuti* ass. nov.). The second has marked presence of *Ludwigia peploides, Cotula coronopifolia*, *Distichlis spicata* and *Paspalum dilatatum*, corresponding to *Polygono-Ludwigietum peploidis* (Steubing et al. 1980). Both are found on the northern and southern plains close to Peñuelas lake, although *Polygono-Ludwigietum* occupies the strip closest to the water (Hauenstein et al., 2009).

17-18. Marsh communities. Two communities of marsh plants were identified, preferably located near the channel which flows into the eastern end of Peñuelas lake. The first, located closer to the water, corresponds to *Scirpetum californiae* (Ramírez & Añazco, 1982), the principal component being totora reed (*Schoenoplectus californicus*), accompanied by *Ludwigia peploides* and *Polygonum hydropiperoides*. The second community, found in a continuous strip a little further away from the water, corresponds to *Loto-Cyperetum eragrostidae* (San Martín et al., 1993), the principal species being *Cyperus eragrostis* and *Carex excelsa* (saw-sedges), accompanied by *Juncus pallescens*

and *J. acutus*; it is a perennial, marshy association, typically found in depressions and on the banks of watercourses, associated with totora reeds or the border of swamp forest with temo (*Blepharocalyx cruckschanksii*) and pitra (*Myrceugenia exsucca*) (Hauenstein et al., 2002; San Martín et al., 2002). In both communities (reed beds and sedge beds), due to the periodic flooding of the site, hydrophytic life forms dominate absolutely, such as typical helophytes (marsh or swamp plants) and hydrophytes (Hauenstein et al., 2009).

19. Aquatic communities. These communities consist principally of hydrophytic species, particularly *Azolla filiculoides*, a free-floating pteridophyte, constituting the *Lemo-Azolletum filiculoidis* association (Roussine & Negre, 1952); moreover the high frequency of *Hydrocotyle ranunculoides*, *H. modesta* and *Eleocharis exigua* allow the existence of *Hydrocotyletum* to be inferred (San Martín et al., 1993), however more censuses would be required to confirm this inference. For example, in the least overgrown part of the spring in the El Abrevadero sector of RN Lago Peñuelas, a small body of water is formed which is colonised by aquatic and marsh species such as: *Azolla filiculoides*, *Gunnera tinctoria*, *Juncus cyperoides*, *Carex excelsa*, *Eleocharis exigua*, *Polygonum hydropiperoides*, *Hydrocotyle modesta* and *H. ranunculoide*s (Hauenstein et al., 2009).

To resume, without considering the variants, 19 plant associations have been described for the Biosphere Reserve.

2.4 Discussion

Flora. When the general floral wealth of the area (420 species) is compared with other surveys done in protected wilderness areas in central Chile, we find for the Maule Region: RN Los Bellotos del Melado – 297 species (Arroyo et al., 2000); RN Los Ruiles – 139 species; RN Los Queules – 104 species (Arroyo et al., 2005). For the Metropolitan Region: Monumento Natural El Morado – 300 species (Teillier, 2003); RN Río Clarillo – approximately 600 species (Teillier et al., 2005). With the exception of the last, all others consist of considerably fewer species than recorded in the La Campana-Peñuelas Biosphere Reserve, demonstrating the floral wealth of this area.

The biological spectrum shows the predominance of therophytes, hemicryptophytes and cryptophytes over other life forms, which is consistent with the xeric conditions of the site, especially during summer, since therophytes (herbaceous plants with short life cycles, annuals or biannuals) and cryptophytes (geophytes or plants with enduring subterranean organs) represent this type of climate very well and are good environmental indicators. Meanwhile the abundance of hemicryptophytes is indicative of human intervention, since this life form accompanies man and corresponds to plants capable of surviving being trodden on and browsed by domestic animals (Cabrera & Willink, 1973; Ramírez, 1988; Grigera et al., 1996).

The general phytogeographic origin of the plants in the Reserve indicates that 23% are introduced species, 49% native and 28% endemic. This confirms the high value of this Biosphere Reserve as an area for the conservation of Chile's native and endemic flora. At the same time, when the relatively high percentage of allochthonous species is considered, and compared to the majority of the studies mentioned above where the values for allochthonous species do not exceed 20%, this would indicate a high level of human intervention in the study area. According to Hauenstein et al. (1988) and González (2000), a percentage distribution in which allochthonous plants reach values of between 20 and 30%

corresponds to the category of "moderate intervention". This high level of intervention is explained by the large flow of visitors and the presence of domestic animals at certain times of year, leading to the arrival of therophytes and hemicryptophytes which, as mentioned previously, correspond for the most part to fast-growing and strongly invasive plants. To this must be added the different soil structure in some sectors of RN Peñuelas under plantations of exotic species (*Pinus radiata*, *Eucalyptus globulus*) and the aggressive colonization by Australian acacias (*Acacia dealbata*, *A. melanoxylon*) (ICSA, 1980; CONAF, 1994).

Arroyo et al. (1995) indicate that the high percentage of endemic species is remarkable in all the protected wilderness areas of Chile's central zone, with values over 40%, which rise to 70% when native plants are included; introduced species thus do not exceed 30%. This is one of the characteristics which highlight the value of these areas as sites where our flora and vegetation units are preserved and protected (Luebert & Becerra, 1998; Hauenstein et al., 2009).

The high number of monocotyledons in the sector should also be noted, especially the abundance of bulb geophytes, which include the majority of species with conservation problems. It should be born in mind that these bear beautiful, brightly coloured flowers, and are especially important in the Bajo Los Lirios sector (CONAF, 1994, 2008; Hauenstein et al., 2009), where there are very brightly coloured and varied Orchidaceae, the Iridaceae, with lilies of the genera *Sisyrinchium* and *Olsynium*, and the tahay (*Calydorea xiphioides*) an "endangered" species which is very scarce throughout the central zone. There are other more frequent but no less beautiful species, like the lahue (*Herbertia lahue*), and flowers of the genera *Alstroemeria, Phycella, Rhodophiala* and *Calceolaria*, which are of aesthetic importance for recreation and use in gardening (Riedemann & Aldunate, 2001; Muñoz & Moreira, 2002).

Vegetation. The total phytosociology of the site consists of 19 plant associations, 6 of which are herbaceous, 7 scrub and 6 forest. With respect to the open espino scrub, also known as "espino or acacia steppe" (Pisano, 1956; CONAF, 1994), it should be made clear that strictly speaking it is not steppe but rather a savannah, as stated by Grau (1992), since the term steppe covers isolated vegetation with denuded surrounding soil and represents cold environments. Savannah on the other hand has isolated trees or thorny shrubs and a rich herbaceous stratum (Cabrera & Willink, 1973). This herbaceous stratum rich in forage species allows use of this type of community, at certain times of year, for grazing by domestic animals in RN Lago Peñuelas; this activity needs to be reviewed urgently by CONAF, since its effects on the biodiversity of the site are unknown.

The predominance of therophytes and geophytes in the biological spectrum of this plant formation is consistent with the climatic conditions and levels of precipitation in the area, since these life forms present morphological and physiological adaptations to the environmental conditions with extended periods of drought, and they are also important elements as food for wild fauna. The lower percentage of phanerophytes is explained by the low levels of precipitation in the area, and probably also the felling of native woody vegetation in the past. The scarcity of chamaephytes is due to the fact that this life form is adapted to conditions of low temperatures and greater altitude, such as are found only on El Roble and La Campana mountains (Cabrera & Willink, 1973; Ramírez, 1988; Grigera et al., 1996).

In the mixed sclerophyllous scrub, the important forms are the sclerophyllous phanerophytes and the therophytes; this also indicates the suitability of this type of plant formation to the climatic conditions of the area. The strong presence of hemicryptophytes indicates human alteration (Hauenstein et al., 1988). Numerous authors have carried out ecophysiological studies on mediterranean scrub species, explaining their ability to adapt to this type of environment, including Mooney & Kummerow (1971) on the drought response of *Flourensia thurifera, Kageneckia oblonga, Lithrea caustica* and *Proustia cinerea*; Montenegro et al. (1979) on the growth dynamic of *Colliguaja odorifera, Lithrea caustica, Satureja gilliesii* and *Retanilla trinervia*; Araya & Avila (1981) on the production of new shoots in scrub species affected by fire; and Avila et al. (1981) on the behaviour of herbaceous stratum species in scrub after a fire.

With respect to sclerophyllous forest, the predominance by phanerophytes and the importance of therophytes and hemicryptophytes are also consistent with the mediterranean climate of the area, since the species present adaptations which enable them to survive intense water stress, e.g. the presence of sclerophyllous leaves (Mooney & Kummerow, 1971), and the fires which are frequent in the area. For protection against fire, many develop a thick peridermis or a lignotuber, structures which enable them produce new shoots after a disaster (Araya & Avila, 1981). This community was classified by Oberdorfer (1960) in the class *Lithraeo causticae-Cryptocaryetea albae* and extends from 31° South to the limit of temperate territory (Aguilella & Amigo, 2001). There is no doubt that areas with this type of vegetation have been most affected by human action (Balduzzi et al., 1981, 1982).

At the same time, the remnants of hygrophilous forest, which requires conditions of greater humidity and precipitation, present absolute predominance of phanerophytes and nanophanerophytes (shrubs) over other life forms, indicating that the area would present high levels of rainfall, which is not the case. The explanation of the presence of this forest with hygrophilous characteristics at the site is based on the fact that it grows above a spring located in the Vega del Álamo sector, also known as the "abrevadero de caballos" [horse water-hole], which generates abundant water all year round, maintaining this community with azonal characteristics (Ramírez et al., 1996; Hauenstein et al., 2009).

The dry grassland is characterised by the predominance of hemicryptophytes, indicating strong human action, since these life forms are adapted to survive being trodden on and browsed by animals introduced by man; and of therophytes, indicating drought conditions (Hauenstein et al., 1988; Ramírez, 1988). In the wet grassland on the other hand, cryptophytes and hemicryptophytes predominate.

Reed beds are the most abundant and variable marsh associations in central-southern Chile, colonising marshes and banks of shallow lotic and lentic bodies of water (Ramírez & Añazco, 1982; Ramírez et al., 1987; San Martín et al., 1993). The same is true of sedge beds, which habitually accompany reed beds, forming a characteristic drier fringe. The principal species, *Cyperus eragrostis* and *Carex excelsa*, have sharp-edged leaves, from which their common name of "saw-sedges" derives (Hauenstein et al., 2002, 2005a).

The hydrophyte community corresponds to *Lemno-Azolletum*, characteristic of eutrophied aquatic environments (Palma et al., 1978); it is mentioned by Ramírez et al. (1987) as very abundant in lakes in Chile's central zone. Likewise, species such as *Hydrocotyle modesta* and

H. ranunculoides are indicators of organic contamination with nitrogen (Hauenstein et al., 2005b), which would corroborate the high trophic levels of Peñuelas lake; at the same time, this body of water and its associated flora form the habitat for a rich avifauna (Strang, 1983).

In this respect, Arroyo et al. (2005) propose, among other measures, the urgent need to complete inventories of flora of all the protected areas of central Chile; likewise they suggest analysing these areas at the scale of small polygons to evaluate their biological importance and vulnerability, elements which should form the basis for an integrated conservation strategy. Likewise, the findings of Armesto et al. (2002) and Simonetti (2004) are important, regarding the need to increase the number of protected areas, both public and private, to increase the size of existing areas, and to make use of the environment which surrounds them and which has suffered intervention, in order to create interconnectivity zones between them to serve as biological corridors. These units of conservation should consider representation of the different types of vegetation (Luebert & Becerra, 1998). Another interesting proposal is that of Elórtegui & Moreira (2002) for La Campana National Park, to zone areas for different types of use. In this context, Simonetti (1995) proposes the need for a model for planning the organization of these protected areas, linking the need to conserve natural resources with their sustainable use, which would be a basic support tool for defining which, where and how possible activities could be carried out, in such a way as would be compatible with conserving biodiversity.

3. Conclusions

The study reported here of the La Campana-Peñuelas Biosphere Reserve registered 420 species of vascular plants, of which 49% are of native origin, 28% correspond to endemic species and 23% to introduced species, respectively. Taxonomically, they are divided into 12 Pteridophytes, 3 Gymnosperms, 290 Dicotyledons (Magnoliopsida) and 115 Monocotyledons (Liliopsida), representing a high floral wealth. However, the percentage of allochthonous plants indicates a moderate degree of human disturbance. Eighteen species present conservation problems (2 Endangered, 13 Vulnerable, 2 Rare, 1 Insufficiently known). The vegetation at the site includes the presence of 19 plant communities, six of which are herbaceous, seven shrub and six arboreal. Important sectors exist of standing out in the Reserve such as: Los Lirios sector, which contains a high percentage of bulb species and numerous threatened species; the Vega del Álamo sector as a valuable remnant of hygrophilous forest; and the Ocoa sector due to the important presence of the endemic Chilean palm tree (*Jubaea chilensis*).

Published in print edition March, 2012

In this book entitled "The Biosphere", researchers from all regions of the world report on their findings to explore the origins, evolution, ecosystems and resource utilization patterns of the biosphere. Some describe the complexities and challenges that humanity faces in its efforts to experiment and establish a new partnership with nature in places designated as biosphere reserves by UNESCO under its Man and the Biosphere (MAB) Programme. At the dawn of the 21st century humanity is ever more aware and conscious of the adverse consequences that it has brought upon global climate change and biodiversity loss. We are at a critical moment of reflection and action to work out a new compact with the biosphere that sustains our own wellbeing and that of our planetary companions. This book is a modest attempt to enrich and enable that special moment and its march ahead in human history.
