1. Introduction

Strongyloidiasis is an intestinal parasitosis found in tropical and subtropical areas, where
the warm climates are suitable for parasite survival (Barr, 1978). It is a common cause of
morbidity and mortality, particularly in developing countries, and infects over one-quarter
of the world’s population (Genta, 1989). Approximately 52 species are known to infect
mammals, birds, reptiles and amphibians (Speare, 1989). The most common globally
distributed human pathogen of clinical importance is Strongyloides stercoralis (Schad, 1989).
Another species, Strongyloides fuelleborni, is a zoonotic parasite that infects primates and is
found sporadically in humans in Africa (Pampiglione & Ricciardi, 1972). S. stercoralis is a
ubiquitous soil-transmitted intestinal nematode that was first reported in 1876 in French
soldiers working in Vietnam. It is unique among helminths in that it completes its life cycle
inside a single human host. A unique feature of strongyloidiasis is the ability of the parasite to
autoinfect the host, which makes S. stercoralis a significant public health problem (Grove, 1989).

2. Epidemiology

The epidemiology of Strongyloides infection is poorly understood because it is difficult to
detect and can be underestimated (Albonico et al., 1999; Viney & Lok, 2007). However, it is
estimated that from 30 a 100 million people are infected worldwide with Strongyloides, and
can range from asymptomatic to multiorgan failure (Genta, 1989). Strongyloides is found in
tropical and subtropical areas and requires specific soil and climate conditions for its
development. In North America, Latin America, Africa and Southeast Asia, the infection is
endemic (Roxby et al., 2009). The risk of acquiring strongyloidiasis is higher in rural areas,
among people who work with soil, and among lower socioeconomic groups (Vadlamudi et
al., 2006; Viney & Lok, 2007). Walking barefoot in areas where human faeces containing the
parasite are deposited increases the probability of acquiring the infection (Grove, 1994).

3. Parasite

S. stercoralis has free-living and parasitic life cycles, and the morphology of each differs.
Parasitic worms are female adults that reproduce by parthenogenesis and measure
approximately 1 - 10 mm in length by 27 -95 μm in width. Free-living adults are
approximately 1 mm, live in the soil, and reproduce sexually; females are slightly larger than males (Speare, 1989). Embryonated eggs are thin-shelled and measure approximately 55 - 60 μm in length and 28 - 32 μm in width. Rhabditiform larvae are the first-stage larvae (210 μm) and develop into free-living larvae or third-stage infective larvae that measure approximately 490-630 μm and are capable of infecting the host (Schad, 1989).

4. Life cycle

The life cycle of *S. stercoralis* includes a parasitic cycle (within human hosts) and an environmental cycle (free-living larvae). The parasitic cycle occurs when the infective filariform larvae penetrate the skin and secrete metalloproteases that facilitate penetration. The main larval route is via the bloodstream to the lungs, where they break into the alveolar spaces within hours after infection, promote haemorrhage, ascend the respiratory tree, are swallowed, and migrate to the intestine. Alternatively, the larvae may migrate directly through connective tissues (Grove, 1994, 1996).

![Life cycle of *Strongyloides stercoralis*](http://emedicine.medscape.com/article/229312-overview#a0104)

Fig. 1. Life cycle of *Strongyloides stercoralis* (modified from Carvalho & Da Fonseca Porto, 2004, and http://emedicine.medscape.com/article/229312-overview#a0104).
The infective larvae reach the small intestine, where they moult twice to become female adult worms. These females reproduce in the absence of males by parthenogenesis. The females are embedded in the intestinal mucosa and produce eggs in the duodenum. The rhabditiform larvae emerge from the hatching eggs and migrate into the intestinal lumen, then pass into the external environment with the faeces. Depending on temperature and humidity, the rhabditiform larvae may have two different life cycles in the environment: an indirect (heterogonic) life cycle, in which the rhabditiform larvae differentiate into free-living adults and release eggs that hatch and transform into infective larvae, or a direct (homogonic) life cycle, in which the rhabditiform larvae may moult directly into filariform larvae and repenetrate the host skin, restarting the cycle (Schad, 1989).

One characteristic that differentiates *S. stercoralis* from almost all other worms is its capacity to replicate within the host. Rhabditiform larvae in the bowel lumen transform into filariform larvae before excretion and invade the intestinal wall or the perianal skin, permitting ongoing cycles of autoinfection, an important feature of strongyloidiasis (Concha et al., 2005).

### 5. Clinical manifestation

The clinical presentation of strongyloidiasis varies with the status of the host’s immune system, and the infection is classified as acute, chronic or severe. Acute infections of strongyloidiasis manifest as a wide spectrum of clinical features ranging from asymptomatic disease to cutaneous (larva currens and urticaria), pulmonary (cough and tracheal irritation), and gastrointestinal symptoms (diarrhoea and constipation), although the majority of *S. stercoralis* infections are resolved (Mahmoud, 1996).

The ability of *S. stercoralis* to establish a cycle of autoinfection within the host results in chronic infections that can persist in an individual for decades. Chronic infections are often asymptomatic, but when symptoms occur they are usually mild, episodic and prolonged, including nausea, vomiting, diarrhoea, constipation, weight loss or cutaneous reactions (Grove, 1989).

Uncontrolled autoinfection of *S. stercoralis* is more likely to occur in immunosuppressed patients, leading to hyperinfection syndrome. The pulmonary phase of hyperinfection due to migrating larvae resembles Löffler syndrome with coughing and wheezing, asthma-like symptoms, haemorrhaging and pneumonia. In the intestine, symptoms include diarrhoea, nausea, vomiting, abdominal pain, and weight loss (Concha et al., 2005; Viney & Lok, 2007). Bacteremia is a common complication of hyperinfection syndrome and is caused by filariform larvae that may lead bacteria from the bowel to the bloodstream with subsequent secretion into the host circulation (Bamias et al., 2010). Pathogens such as *Streptococcus bovis, Escherichia coli, Klebsiella pneumonia* or *Enterobacter cloacae* are found during fatal complications of strongyloidiasis (Link & Orenstein, 1999). The mortality rate of dissemination associated with bacterial infections can reach approximately 90% (Igra-Siegman et al., 1981).

Dissemination occurs upon larval migration to organs beyond the range of the pulmonary phase, such as the liver, heart, lymph nodes, gallbladder, kidneys, pancreas, and brain (Keiser & Nutman, 2004). Petechiae and purpura have also been reported in disseminated cases as a result of larval migration through vessel walls, which promotes haemorrhage (Basile et al., 2010). Others complications of disseminated strongyloidiasis can occur and include syndromes such as cholecystitis, pancreatitis, paralytic ileus, intestinal perforation...
or infarction, peritonitis, and sepsis (Krishnan et al., 2006). Although unusual, brain involvement can occur in disseminated infections, with symptoms including headache, focal seizures, altered mental state, secondary bacterial meningitis and coma (Dutcher et al., 1990).

6. Hyperinfection syndrome

Since 1966, studies have reported that autoinfection may result in the dissemination of worms; denoted hyperinfection syndrome, the number of worms increases significantly, and worms are detectable in extraintestinal regions, with a mortality rate above 80% (Siddiqui & Berk, 2001). High-risk factors for hyperinfection and dissemination include corticosteroid therapy, malignancies, transplantation, malnutrition, hypogammaglobulinemia, and viral infections such as HIV (Human Immunodeficiency Virus) and HTLV-1 (Human T-Lymphotropic Virus Type 1) (Concha et al., 2005).

6.1 Corticosteroids

In recent decades, hyperinfection syndrome has increased significantly with the use of immunosuppressive drug therapy. Corticosteroids are widely prescribed drugs with potent immunosuppressive effects and are a major risk factor for the transformation of chronic strongyloidiasis into hyperinfection, which has a higher index of mortality (Armignacco et al., 1989; Al Maslamani et al., 2009). Corticosteroids are involved in the treatment of several diseases that are considered immunological abnormalities, such as lymphoma, rheumatoid arthritis, leprosy, chronic obstructive pulmonary disease (COPD), and polymyositis, leading to fatal hyperinfection in many cases (Keiser & Nutman, 2004). However, the role of corticosteroids in susceptibility to severe *S. stercoralis* infection is poorly understood. One hypothesis is that both endogenous and exogenous corticosteroids promote immunosuppression by decreasing the number of inflammatory cells, such as eosinophils and mast cells, and suppressing the transcription of several cytokines. In addition, corticosteroids increase the apoptosis of Th2 lymphocytes (Genta, 1989). Corticosteroids may also have a direct effect on female worms by increasing the production of ecdysteroid-like molecules, hormones that control moulting in insects and possibly helminths (Genta, 1992). An increase in these molecules increases the moulting rate and transforms rhabditiform larvae into filariform larvae, increasing the worm burden and promoting hyperinfection and dissemination (Genta, 1992; Siddiqui et al., 2000).

6.2 Hematologic and others malignancies

Patients with hematologic malignancies have a high prevalence of *S. stercoralis* infection when compared with the global index. The reported cases of hematologic malignancies and *S. stercoralis* hyperinfection syndrome are associated with glucocorticoid treatment. The malignancy usually associated with *S. stercoralis* is lymphoma that is being treated with chemotherapy. Moreover, lung cancer has been associated with hyperinfection during the administration of immunosuppressive chemotherapy (Keiser & Nutman, 2004).

6.3 Transplantation

Hyperinfection syndrome is associated with transplants, and the progression of chronic intestinal infection before transplantation appears to be the most common mechanism.
Hyperinfection cases following organ transplant principally occur during the initial months after transplantation, but the infection was acquired before transplantation in the majority of cases (Roxby et al., 2009). Higher mortality rates occur from extraintestinal strongyloidiasis, which in most of these cases are related to corticosteroid therapy to treat rejection (Keiser & Nutman, 2004).

Renal transplants are most commonly associated with hyperinfection, which is related to immunosuppressive treatments (DeVault et al., 1990; Rajapurkar et al., 2007; Valar et al., 2007). Cases of hyperinfection have been described in transplant recipients of other organs, such as the liver (Vilela et al., 2008; Rodrigues-Hernandez et al., 2009), heart (Schaeffer et al., 2004), pancreas (Ben-Youssef et al., 2005), lung (Balagopal et al., 2009), and intestine (Patel et al., 2008). Hyperinfection in hematopoietic stem cell transplant patients may be due to immunosuppressive therapies (Dulley et al., 2008; Wirk & Wingard, 2008).

6.4 Malnutrition
An important cause of immunodeficiency that is related to hyperinfection is malnutrition, particularly in developing countries. Malnutrition promotes disruption of the intestinal mucosa, impairing the host’s ability to expel the parasite from the gut (Olsen et al., 2009).

6.5 Hypogammaglobulinemia
Patients with immunodeficient conditions, such as hypogammaglobulinemia, may develop fatal hyperinfection. Case reports show that hypogammaglobulinemia is refractory to prolonged anthelmintic therapy (Brandt de Oliveira et al., 1981; Seet et al., 2005).

6.6 HIV
Although HIV infection predisposes a patient to hyperinfection due to immunosuppression, few cases of S. stercoralis and AIDS have been described (Marcos et al., 2008). The association between S. stercoralis and HIV principally occurs in endemic areas (Siddiqui & Berk, 2001). The hyperinfection syndrome can occur in patient with HIV with immune reconstruction syndromes increased after starting of highly active antiretroviral therapy (Brown et al., 2006). On the other hand, the infection with Strongyloides may contribute to serious nutritional deficiencies in HIV-infected individuals, such as anorexia and malabsorption (Lindo et al., 1998). However, the immunobiological and immunoregulatory mechanisms involving HIV and strongyloidiasis remain unclear.

6.7 HTLV-1
HTLV-1 is a virus that infects T cells and induces lymphocyte proliferation with the production of a Th1-type immune response in humans. The genome of the HTLV-1virus is diploid and, following interaction with the immune system, HTLV-1 enables the transcription of the viral DNA by integrating into the host genome effectively evading immune surveillance without killing the host (Iriemenan et al., 2010). Strongyloidiasis is strongly associated with HTLV-1, which predisposes patients to severe infections by depressing cell-mediated immunity or IgE responses (Grove, 1996; Carvalho & Da Fonseca Porto, 2004). Strongyloides and HTLV-1 may promote the Th1-type response in patients, increasing interferon levels and decreasing Th2-type responses, such as interleukin 4 (IL-4), IL-5, IL-13, and IgE, important host defences against helminths, and a decrease in this response allows not only an increasing in autoinfection but also decreased parasite killing.
In addition, this association reduces the efficacy of anthelmintic drugs, increasing the prevalence of infection (Montes et al., 2009; Iriemenam et al., 2010). Stool examinations should be performed with special attention to detect *S. stercoralis* larvae in all patients infected by HTLV-1 (Carvalho & Da Fonseca Porto, 2004).

### 7. Host-parasite interaction

The relationship between *S. stercoralis* and its host is complex, and little is known about the immunomodulatory mechanisms that regulate this interaction. Different factors are involved, including the capacity of the parasite to replicate, the adequacy of the host immune response, and the ability of the parasite to evade those responses (Grove, 1994; Trajman et al., 1997).

#### 7.1 Cellular immune response

During helminthic infection, Th2-type cell-dependent host defences that involve CD4 cells are developed (Maizels & Yazdanbaksh, 2003; Anthony et al., 2007). In human hosts and animal models, the cellular immune response to *Strongyloides* infection is characterised by intraepithelial and tissue eosinophils, neutrophils and mast cells with Th2-type production of cytokines such as IL-4, IL-5 and IL-13. Conversely, Th1-type responses are down-regulated during nematode infection (El-Malky et al., 2003; Paterson et al., 2008; Iriemenam et al., 2010).

##### 7.1.1 Eosinophils

Eosinophils are essential against nonphagocytosable parasites, such as *Strongyloides*, that cannot be ingested because of their large size. Eosinophils defend the host by attacking the parasite via the FceRI receptor, capturing antigens from the worms and presenting the antigens to T cells to initiate an antigen-specific immune response (Galioto et al., 2006; Padigel et al., 2006; Iriemenam et al., 2010). Others mechanisms may be involved, including antibody-dependent cellular cytotoxicity (ADCC) mediated by eosinophils on the parasite surface, which releases toxic molecules in an attempt to eliminate the parasite (Ligas et al., 2003; Klion & Nutman, 2004).

##### 7.1.2 Mast cells

Mast cells have an important role in the defence against *S. stercoralis* by inhibiting the invasion of the adult worm into the intestinal epithelium, promoting the stimulation of gut motility, mucus release and expulsion of the parasites. In addition, mast cells induce the attraction and modulation of eosinophils (Kobayashi et al., 1998; Concha et al., 2005).

#### 7.2 Cytokines

Strongyloidiasis promotes the robust Th2-type immune response with the production of cytokines, such as IL-3, IL-4, IL-5, IL-6, IL-9, IL-10 and IL-13. Contrarily, Th1-type responses are reduced during nematode infection (Wilkes et al., 2007; Patel et al., 2009). IL-3 is important during *Strongyloides* infection stimulates the synthesis of potent mast cells and basophils enhancing the function of these cells (Abe et al., 1993). In addition, IL-3 can enhance the levels of intra-cellular IL-4 upon activating basophils, with anti-IgE and IL-3 contributing to an increase in eosinophils (Kimura et al., 2006; Lantz et al., 2008).
IL-4 has multiple immunoregulatory functions, including T-cell growth factor activity, B-cell regulation, serum IgE level enhancement, and stimulation of the growth and/or differentiation of macrophages, hematopoietic cells, and mast cells (Urban et al., 1991; Negrão-Correa et al., 2006; Wilkes et al., 2007). IL-4 decreases the fecundity and survival of adult worms and increases intestinal smooth muscle contraction, facilitating the expulsion of the parasite (Concha et al., 2005).

IL-5 regulates the production of eosinophil myelocyte precursors in bone marrow, the development of mature eosinophils after helminth infection and, in most instances, the production of a number of other cytokines, including IL-4 and IL-13, and chemokines such as RANTES and eotaxin (Herbert et al., 2000; Klion & Nutman, 2004; Mir et al., 2006).

IL-13 also participates in the defence mechanisms against helminths, promoting an increase in the intestinal fluid content and increased smooth muscle contractility, a phenomenon that may contribute to worm expulsion (P'orto et al., 2001; Shea-Donohue & Urban, 2004; Patel et al., 2009).

7.3 Humoral immune response
The humoral immune response complements defence mechanisms against strongyloidiasis with the production of immunoglobulins by plasma cells. Several immunoglobulins, such as IgE, IgG and IgM, are essential for the elimination of the parasite (Ligas et al., 2003; Machado et al., 2005).

IgE antibodies can mediate the activation of accessory cells and the recognition of parasite antigens, promoting goblet cell mucus secretion and the degranulation of mast cells that release mediators affecting parasite survival (Machado et al., 2009). IgG and IgM can transfer immunity against the human parasite in the presence of the complement system and neutrophils (Abraham et al., 1995; Vadlamudi et al., 2006).

Laboratory models have suggested that both T and B cells mediate the immune response through an increase in immunoglobulins, eosinophils and mast cells and hyperplasia of goblet cells, which require interleukins and chemokines for their development and activation. In strongyloidiasis, dexamethasone seems to primarily suppress cytokines such as IL-1β, IL-4, VEGF, TNF-α, IFN-γ, IL-3, IL-4, IL-5, IL-10 and IL-12 and decreases the production of IgG and IgE antibodies during S. venezuelensis infection (Machado et al., 2011; Tefé-Silva et al., 2012).

7.4 Other responses
The complement system activates both classical and alternative pathways with chemoattraction and binding of granulocytes in association with effector cells, which are essential against S. stercoralis (Vadlamudi et al., 2006). Studies have reported that complement component C3 is required during S. stercoralis infection and facilitates eosinophil degranulation and larval death during the innate immune response (Kerepesi et al., 2006).

Strongyloides infection induces the production of leukotrienes, which are required to invoke the protective expulsion of parasites. Leukotrienes play an important role in controlling parasite burdens, as well as in altering the parasite reproductive cycle and eliminating the S. venezuelensis parasite (Machado et al., 2005).

8. Pathology
The pathology of strongyloidiasis differs in different stages of infection.
8.1 Acute infection
The obligate pulmonary phase of the parasite’s life cycle typically occurs within hours after infection. During larval passage through the lungs, the parasite induces haemorrhage in the alveolar spaces, inflammatory infiltrate, and, occasionally, granuloma (Kinjo et al., 1998). Histopathological analyses of human intestines have shown that S. stercoralis eggs and adult females colonise the duodenum and upper jejunum. Studies have also demonstrated the presence of oedema, duodenal villous atrophy, and crypt hyperplasia with disrupted epithelium due to the inhibition of cell proliferation and apoptosis (Coutinho et al., 2006; Werneck-Silva et al., 2006). Surface damage, ulceration, an increase in mucus secretion and functional changes in the intestine have also been reported. In many cases, the eosinophil infiltrates are associated with the intensity of the infection (Rivasi et al., 2006; Kishimoto et al., 2008).

8.2 Hyperinfection syndrome
The histology of lungs affected by hyperinfection syndrome revealed alveolar haemorrhage with large numbers of larvae in the alveoli, septa, pleurae and blood vessels. Many larvae were present throughout the walls of the tracheobronchial tree, with an increase in number toward the upper respiratory tract. Larvae in the lungs provoked inflammatory infiltrate

Fig. 2. Histopathology of Strongyloides stercoralis in the lungs and intestine of a 48-year-old woman with a gastric carcinoid tumor treated with chemotherapy. A and B: Pulmonary parenchyma. Note the presence of larvae in alveolar space (arrow). C and D: Female worms in the duodena (arrows). HE stain.
and were occasionally walled off by granulomas. Bronchopneumonia is probably a consequence of tissue damage inflicted by the invading larvae (Zumla & James, 2002). In the human intestine, hyperinfection results in mucosal oedema, acute inflammation, mucosal haemorrhage, and focal ulceration with numerous *S. stercoralis* larvae, adult worms and ova embedded within the small bowel villi (Sathe & Madiwale, 2006; Al Maslamani et al., 2009).

![Fig. 3. Histopathology of the lungs of rats in an experimental model of strongyloidiasis on day 3 post-infection: A and B: Controls; C and D: Infected with *S. venezuelensis*. Note the scarce hemorrhagic foci with larvae in the alveolar spaces (arrows); E and F: Infected with *S. venezuelensis* and treated with dexamethasone. Note the prominent hemorrhagic foci showing larvae in the alveolar spaces (arrow). HE stain.](https://www.intechopen.com)
8.3 Hyperinfection syndrome in experimental models
Animal models are important for understanding the mechanism of hyperinfection. Studies in experimental models of *S. venezuelensis* infection have reported that filariform larvae were surrounded by inflammation mediated by eosinophils and mast cells in the lungs. The infection also promoted an important granulomatous response, sometimes entrapping the larvae, which is probably an attempt by the host to contain the parasite. In addition, airway

Fig. 4. Histopathology of the duodena of rats in an experimental model of strongyloidiasis on day 14 post-infection: A and B: Controls; C and D: Infected with *S. venezuelensis*. E and F: Infected with *S. venezuelensis* and treated with dexamethasone on day 14 post-infection. Note the massive mucosal invasion of fertile eggs and adult parasites, accompanied by erosion of the intestinal epithelial layer. HE stain.
remodelling similar to asthma, characterised by hyperplasia of goblet cells and increased bronchiolar wall thickness caused by oedema, hypertrophy of smooth muscle cells, neovascularisation and collagen deposition, was reported. In contrast, immunosuppression with dexamethasone interferes with the pulmonary cycle of Strongyloides venezuelensis infection and promotes greater haemorrhage, which is provoked by the substantial quantities of larvae that pass into the alveolar spaces, accompanied by a decrease in eosinophil and mast cell migration and impaired formation of granulomas (Tefé-Silva et al., 2008). In addition, dexamethasone treatment inhibited airway remodelling, contributing to the dissemination of the parasite (Tefé-Silva et al., 2012).

In the small intestine of rodents infected with S. venezuelensis, females and fertile eggs were observed in the wall of the gastrointestinal tract and invading the intestinal mucosa, with increased inflammatory exudate and eosinophils (Machado et al., 2005). Dexamethasone treatment promoted increased mucus production, which progressed to a massive mucosal invasion of fertile eggs and adult parasites that was accompanied by the erosion of the intestinal epithelial layer. Interestingly, the inflammatory response was relatively inconspicuous. Proliferative activity increased in the crypts and the villous fusion, resulting in an apparent reduction in the number of intestinal epithelial cells. In addition, dexamethasone enhanced parasite fertility and proliferation, with dissemination of the larvae to other visceral organs, such as the spleen, kidneys, heart, liver and brain (Machado et al., 2011).

Mice infected with S. venezuelensis and treated with dexamethasone showed increased blood neutrophil numbers and a reduction in eosinophil and mononuclear cell numbers in the blood, bronchoalveolar cells, and peritoneum when compared to S. venezuelensis infection in the absence of dexamethasone. In addition, dexamethasone impaired the host immune response, decreasing the production of cytokines such as tumour necrosis factor (TNF), interferon (IFN), interleukin-3 (IL-3), IL-4, IL-5, IL-10, and IL-12 in the lungs and circulating antibodies such as IgG, and IgE but increasing the overall parasite burden in the intestines and faeces (Machado et al., 2011).

9. Diagnosis

Strongyloidiasis is diagnosed on the basis of suspicion in patients with clinical signs and symptoms of the disease; however, in approximately 50% of cases, the infection is asymptomatic, complicating diagnosis. In some cases, diagnosis is difficult despite a low intestinal worm load and larval excretion in the faeces (Rajapurkar et al., 2007). The classic triad of urticaria, abdominal pain and diarrhoea is suggestive of a diagnosis of strongyloidiasis. Parasites are usually found in the faeces; they are sometimes also seen in other body fluids or in tissue samples (Basile et al., 2010). The parasitological diagnosis is usually made after an examination of the faeces, and several diagnostic methods can be used to detect S. stercoralis, including stool examination, a modified Baermann technique, and stool culture on a blood agar plate. Enzyme-linked immunosorbent assays (ELISA) are used for serological diagnosis and have proven valuable in detecting both symptomatic and asymptomatic strongyloidiasis infection, with a high specificity for detecting IgG antibodies to S. stercoralis (Basile et al., 2010). In patients with a disseminated infection, the diagnosis is relatively straightforward, given the high numbers of larvae that exist in the stool and, usually, in the sputum. White blood
cell numbers may be elevated. Although an increase in eosinophils frequently occurs during infection, studies have shown that an absence of eosinophilia does not exclude a diagnosis of strongyloidiasis (Krishnan et al., 2006). Diagnosis through imaging is usually possible. Chest radiographs of some patients have shown infiltrate consistent with Loeffler’s syndrome. Methods such as bronchoalveolar lavage and sputum culture are used to diagnose disseminated strongyloidiasis (Williams et al., 1988, Yassin et al., 2010). Duodenal fluid aspiration and intestine biopsy or the use of Enterotest® may be required to detect the Strongyloides parasite (Yassin et al., 2010).

10. Treatment

Early identification of the disease and anthelminthic treatment results in a better prognosis for strongyloidiasis and, in many cases, prevents a fatal infection (Basile et al., 2010). S. stercoralis is resistant to anthelmintic drugs, and the parasite has the capacity to replicate and increase the worm burden again (Grove, 1996). Thiabendazole, albendazole, and mebendazole are effective drugs against S. stercoralis. Thiabendazole was the drug of choice for treatment of strongyloidiasis, with a cure rate of up to 80%. Albendazole has variable therapeutic efficacy but has been used in hyperinfection syndrome and remains a viable treatment alternative to ivermectin. Mebendazole can be used to treat strongyloidiasis but is not recommended because of an association with liver dysfunction (Rajapurkar et al., 2007). Recently, there has been a change in the treatment of strongyloidiasis, as more studies support the choice of the drug ivermectin, which is effective at killing worms in the intestine. In patients with hyperinfection syndrome, ivermectin is considered the first-line therapy, and longer courses of treatment are indicated (Roxby et al., 2009).

Efficient treatment of strongyloidiasis depends on several factors that can decrease the efficacy of the drugs used for treatment, such as immunodeficiency, corticosteroid use, or co-infection with HTLV-1 (Vadlamudi et al., 2006). Prolonged or repeated treatment may be required in patients receiving immunosuppressive drugs. Other measures, including decreasing the dosage of corticosteroids, discontinuing immunosuppressive therapies and treating bacterial infections, are essential elements in the treatment of these patients. In all cases, patients with strongyloidiasis, regardless of the severity of symptoms, must be treated to prevent long-term complications (Montes et al., 2010).

11. Control

Like other soil-transmitted nematode infections, strongyloidiasis can be controlled by improving sanitary conditions and properly disposing of faeces. Infected patients should be treated, even if they are asymptomatic, to preclude the possible onset of autoinfection. Immunosuppressants are contraindicated in these patients. Personal hygienic measures like proper protection of the skin to prevent contact with infected soil, community education about protective and hygienic measures, and prompt treatment of diagnosed cases would help prevent the disease (Vadlamudi et al., 2006).

12. Conclusion

Strongyloidiasis is an infection with a tendency to become chronic with an indolent course. However, in immunocompromised patients, especially those treated with corticosteroids,
hyperinfection syndrome can compromise the prognosis of the patient. The mortality rates of hyperinfection are high, making *Strongyloides* infection an important global health problem. It is important to understand the biology and immunology of infection with *S. stercoralis* and the altered courses of infection that may occur when immune regulation is compromised. Clinicians who are aware of the possibility of hyperinfection are better equipped to diagnose, treat, or altogether prevent the fatal consequences of this lethal nematode.

in rats. American Journal of Tropical Medicine and Hygiene, Vol.79, No.4, (October), pp. 571-578, ISSN 0002-9637

Tropical Medicine has emerged and remained as an important discipline for the study of diseases endemic in the tropic, particularly those of infectious etiology. Emergence and reemergence of many tropical pathologies have recently aroused the interest of many fields of the study of tropical medicine, even including new infectious agents. Then evidence-based information in the field and regular updates are necessary. Current Topics in Tropical Medicine presents an updated information on multiple diseases and conditions of interest in the field. It includes pathologies caused by bacteria, viruses and parasites, protozoans and helminths, as well as tropical non-infectious conditions. Many of them are considering not only epidemiological aspects, but also diagnostic, therapeutic, preventive, social, genetic, bioinformatic and molecular ones. With participation of authors from various countries, many from proper endemic areas, this book has a wide geographical perspective. Finally, all of these characteristics, make an excellent update on many aspects of tropical medicine in the world.
