1. Introduction

Vitiligo is largely classified into segmental and non-segmental types (Table 1).\(^1\) This classification is based on the original report by Koga in 1977.\(^2\) Koga proposed that vitiligo in a non-dermatomal distribution be referred to as Type A and vitiligo in a dermatomal distribution be Type B, the latter of which corresponds to what is known today as segmental vitiligo (SV). Since then, the distinctive characteristics of SV have been described.\(^3\)-\(^6\) Recently, it was proposed that vitiligo be classified into four major types: segmental, non-segmental, mixed, and unclassified.\(^7\)

The incidence of SV is not well-established because different investigators report variable percentages of patients having SV. El-Mofty \textit{et al} reported that only 5\% of patients with vitiligo had the segmental type.\(^8\) Koga and Tango described that in their population, 27.9\% had SV.\(^3\) Several studies in Korea revealed the prevalence of SV to range from 5.5\% to 29.6\%.\(^4\),\(^9\),\(^10\) The typical lesion of SV is not significantly different from that of NSV. Both can initially appear as focal vitiligo, which involves a small area.\(^11\) However, SV has a distinct natural history and unique clinical features.\(^1\),\(^3\),\(^4\) In addition, SV shows different therapeutic characteristics when compared with NSV.\(^1\),\(^12\)

SV can appear at any age, but the majority of cases occur early in life between the ages of 5 and 30 years old. Koga and Tango reported that 82\% of type B vitiligo (SV) patients noticed their first depigmented patches before the age of 30.\(^3\) In the pivotal SV study by Hann and Lee, the mean age of onset was 15.6 years, and SV developed before 10 years of age in 41\% of cases, and before 30 years of age in 87\%.\(^4\) In our study, the mean age of onset was 19.8 years; 32\% of SV started before 10 years of age and 62\% before 20 years of age.\(^6\)

SV typically presents with unilateral involvement of depigmented macules surrounded by normal skin. The color of the macules is usually white and more distinguishable with Wood’s light examination. However, macules may have a more irregular border and less homogeneous pattern of pigment loss than NSV.\(^11\) Trichrome vitiligo, which is characterized by both depigmented and hypopigmented macules, is reported in SV.\(^13\)

SV shows a quasi-dermatomal mode of distribution, but seems to be different from the pattern of herpes zoster. SV often involves a segment that includes the parts of several dermatomes and may at times, go over the midline partially. Some cases may involve lines or large bands consistent with Blaschko’s lines.\(^14\),\(^15\) There is no preferential distribution between right and left sides of the body. Very rarely, SV involves two or more different segments with ipsilateral or contralateral distribution. Lee and Hann reported that 5 of 240 SV cases showed bilateral SV on the same or different dermatomes that appeared on both sides of the body.\(^16\)
The face is the most common site of SV regardless of gender (Figure 1). According to the Hann and Lee study, 51% of SV involved the face, 25% the trunk (Figure 2), and 11% the extremities. In our own study, 54% of SV involved only the face. An additional 17% had both face and neck involvement of SV (Figure 3).

![Fig. 1. Segmental vitiligo on the face.](image1)

![Fig. 2. Segmental vitiligo on the abdomen.](image2)
Fig. 3. Segmental vitiligo on the face and neck.

Hann et al proposed the original classification of the SV distribution of the face. This was revised to include 6 types depending on pattern and area of involvement. This classification may be valuable for certain aspects of prognosis, such as the likely degree and path of lesional spread. SV is often associated with the occurrence of white hair (i.e., poliosis, leukotrichia) in lesional skin. SV tends to involve the hair compartment soon after onset compared to NSV. Hann and Lee reported that poliosis was found in 49% of 208 patients with SV. The eyebrow (Figure 4) and eyelashes commonly show white hair and other hair-bearing sites including the scalp, pubis, and axilla can be involved. However, it is very difficult to notice the presence of white hairs on other areas of the body with the naked eye because the hairs consist of tiny, thin vellus hairs. We examined 82 patients for the presence of leukotrichia in SV lesions using a digital portable microscope. All of the patients demonstrated leukotrichia independent of age and disease duration (Figure 5). The amount of white hair was variable. These results suggest that a very high percentage of patients with SV have associated leukotrichia.

It has been reported that SV usually spreads within a segment in a short period of time and then tends to stop. However, in our own study, we observed 87 patients who had SV for mean of 29.5 months (maximum 150 months), 19 cases (21.8%) showed disease progression 4 years after disease onset (2011 IPCC presentation). Therefore, more long-term follow-up data are needed in order to more accurately understand the natural course and the long-term recurrence rate of SV.
Fig. 4. White hairs of the eyebrow in segmental vitiligo can be seen.

Fig. 5. Leukotrichia in a segmental vitiligo lesion can be seen easily using portable digital microscopy (magnified 30x)

It has been proposed that the rare instance of SV progresses into a generalized form, that this be called mixed vitiligo.\textsuperscript{19} However, this likely represents only the rare circumstance of concurrent SV and NSV rather than its own independent vitiligo type. SV is not usually accompanied by other autoimmune diseases contrary to NSV.\textsuperscript{1,3,8} However, Park \textit{et al} reported that about 9.5\% of SV cases were associated with other diseases\textsuperscript{20} and Hann \textit{et al} described that 6.7\% of 208 patients had an associated disease, including atopic dermatitis, halo nevus, thyroid disease, diabetes mellitus, and alopecia areata.\textsuperscript{4}

2. Treatment of segmental vitiligo

Segmental vitiligo (SV) is a distinct type of vitiligo in terms of its clinical features, natural course, and response to treatment, that make it distinguishable from non-segmental vitiligo (NSV). In SV, white macules are usually localized to one segment on only one side of the body, however, in NSV white macules can occur at any body location and disease activity tends to persist throughout the life of the patient. Thus, the course of SV is predictable while that of NSV is unpredictable. Treatment guidelines of SV may be easier to determine than those of NSV.

Until now, many articles about vitiligo treatment have been published. However, many of these studies were not randomized, controlled, and double-blinded, but rather retrospective studies or case reports. In addition, many studies did not distinguish between the types of vitiligo or they did not provide demographic information about SV in detail. Thus, reliable publications about the treatment of SV are scarce.

The treatment modalities for vitiligo largely consist of medical and surgical therapies. Medical management includes topical corticosteroids and immunomodulators, and phototherapy such as narrow-band UVB (NB-UVB) and excimer laser. If medical treatment is unsatisfactory, surgical treatments such as autologous skin grafting may be considered. Taïeb and Picardo presented treatment guidelines for vitiligo in a review.

2.1 Topical corticosteroids

Topical corticosteroids have been used for the treatment of vitiligo for decades. There have only been a few studies about the effects of topical corticosteroids in SV.

Koga evaluated the effect of topical corticosteroids in vitiligo patients. In this study, only five patients with SV were included and received topical steroid therapy (0.12% betamethasone-17-valerate, 0.01% fluocinolone acetonide, or 0.1% triamcinolone acetonide cream or ointment) for a minimum of 2 months. However, no improvement was found in any of these patients.

Khalid and Mujtaba treated forty SV patients with 0.05% clobetasol propionate cream twice daily. Therapy was interrupted every 6 weeks for a 2-week treatment-free period. Some
response was observed in the majority of patients (79%, 30 out of 38) and more than 50% repigmentation was observed in 34% (13) of patients. The best results were found on the face. Out of the 23 patients who presented within 1 year of SV onset, 11 (47.8%) showed more than 50% repigmentation; on the other hand, only two out of 15 (13.3%) patients who presented after one year of the onset of SV achieved the same degree of response. The side effects were mild skin atrophy in six patients, telangiectasias in four patients, and acneiform papules in eight patients. These results suggest that disease duration may be an important indicator of prognosis because most of the patients showing more than 50% repigmentation presented within one year of SV onset.

2.2 Topical immunomodulators (calcineurin inhibitors)
Several studies have demonstrated the efficacy of tacrolimus ointment and pimecrolimus cream in the treatment of vitiligo patients. However, most of them did not disclose the inclusion of SV. Silverberg et al assessed the efficacy of topical tacrolimus ointment in the treatment of childhood vitiligo.23 Fifty-seven patients were treated with tacrolimus ointment (0.03% or 0.1%) once or twice daily for a minimum of three months. In their series, 37% of the patients had SV, most commonly of the head and/or neck. Among the SV patients, 86% responded to tacrolimus ointment, especially those with facial involvement (94%). One patient showed complete repigmentation on the chin and neck after eight weeks of summer sun exposure along with twice daily tacrolimus 0.03% ointment. Udompataikul et al evaluated the effectiveness of 0.1% tacrolimus ointment in 42 vitiligo patients, of whom eleven patients had SV.24 The overall response rate, defined as at least some evidence of repigmentation, was 76% and the response rate for SV was 77%.

2.3 Phototherapy
Phototherapy has been widely used for the treatment of vitiligo. However, most studies about phototherapy in vitiligo were performed in patients with NSV.
1. NB-UVB
Anbar et al evaluated the clinical response of vitiligo patients to NB-UVB. Their study included 150 patients with SV (10%) or NSV (90%).25 NB-UVB therapy was given twice weekly. In the NSV group, 48% of patients showed a marked response (more than 75% repigmentation) and 27% showed a moderate response (between 26% and 75% repigmentation). However, in the SV group, 92.3% showed no more than a mild response (less than 25% repigmentation) to treatment regardless of the lesion site, and only 7.7% of SV patients showed a moderate response. NB-UVB microphototherapy uses a device that delivers a focused beam with wavelengths from 300 to 320 nanometers (nm) with a peak emission of 311 nm. Lotti et al evaluated the effectiveness of UVB microphototherapy for eight SV patients for six months.26 Five patients achieved normal pigmentation on more than 75% of their treated areas.
2. PUVA
Tallab et al evaluated the efficacy of systemic psoralen and ultraviolet A (PUVA) in the treatment of vitiligo retrospectively.27 Thirty-two patients with vitiligo were studied, including five patients with SV. All of the SV patients showed no or poor repigmentation. They concluded that SV was very resistant to PUVA therapy.
3. Excimer laser
The 308 nm excimer laser has demonstrated promising efficacy and appealing side effect profile for localized vitiligo.\textsuperscript{28,29} Compared with conventional NB-UVB, excimer laser generally provides more rapid repigmentation in limited forms of vitiligo. Do et al performed a retrospective analysis to evaluate the treatment response to excimer laser in SV patients.\textsuperscript{30} Eighty patients with SV were included. Repigmentation was graded as: grade 0, no repigmentation; grade 1, 1-24%; grade 2, 25-49%; grade 3, 50-74%; grade 4, 75-99%; grade 5, complete repigmentation. The mean grade of repigmentation was 2.3 after a mean of 20.6 months of treatment; 23.8% showed grade 4, 20% showed grade 3, and 56.2% showed grade 1-2 repigmentation. However, none of them achieved complete repigmentation. They observed that SV had a better repigmentation response rate when the excimer laser was used at earlier stages of the disease for longer treatment durations with high cumulative UV energy. However, the limitation of their study was that many patients received other concurrent treatments such as oral corticosteroids, topical steroids, or topical tacrolimus ointment during the study period.

4. Miscellaneous Therapies
We retrospectively evaluated the effect of phototherapy in nine patients with SV depending on the disease duration.\textsuperscript{31} All patients except one had SV for longer than two years when they started on a phototherapy regimen of PUVA, NB-UVB, or excimer laser. All patients showed a poor response to phototherapy irrespective of the type of phototherapy administered. Our results suggest that phototherapy is not helpful in long-duration SV. It has been reported that the combination of NB-UVB and tacrolimus ointment is effective in vitiligo.\textsuperscript{32} However, this combination treatment of NB-UVB and tacrolimus ointment in SV is limited to case reports.

We presented two cases of recent onset SV that showed good or excellent response to targeted phototherapy (Dualight\textsuperscript{®}) in combination with drug therapy.\textsuperscript{33} Our results suggest that SV can be improved with combination therapy if SV onset is recent, emphasizing that early treatment may be essential for this type of vitiligo. In addition, we reported a case of SV that showed a marked response to combination NB-UVB and 0.1% topical tacrolimus compared with 0.1% topical tacrolimus alone.\textsuperscript{34} This case suggests that combination therapy is necessary for SV. Low-energy helium-neon laser (632.8 nm) has applications in a variety of clinical conditions including vitiligo. Yu et al evaluated the efficacy of the helium-neon laser on thirty patients with SV on the head and/or neck.\textsuperscript{35} Marked repigmentation (more than 50%) was observed in 60% of patients.

2.4 Surgical treatment
Generally, surgical treatment is indicated for stable vitiligo that does not respond to medical treatment.\textsuperscript{36} Patients with SV are considered a good candidates for surgical treatment.\textsuperscript{21} Although medical treatment is often helpful in SV, complete repigmentation is almost always difficult to obtain. Thus, surgical treatment is necessary for complete repigmentation in many cases of SV. Surgical treatment includes autologous epidermal grafting (Figure 6), mini-grafting, and transplantation of epidermal cell suspensions.\textsuperscript{21} Gupta and Kumar analyzed a retrospective, uncontrolled case series and literature review of 143 patients treated with epidermal grafting. They found that repigmentation success rates for generalized and segmental (including focal) vitiligo were 53 and 91\%, respectively.\textsuperscript{37} In epidermal grafting surgeries, oral corticosteroids may be a helpful adjunct. We reported that in a case of SV with failure to repigment with surgery alone, that response occurred
when oral corticosteroid was added to the grafting procedure. In addition, we also presented that achieving better results in SV may be contingent on combination therapy utilizing epidermal grafting with systemic corticosteroids. SV may continue to spread even a few years after onset of disease. We presented a case of SV which continued to spread after epidermal grafting; the new lesions did not involve the area of previous epidermal grafting, but repeated epidermal grafting was successful. This case indicates that epidermal grafting can be useful for the treatment of SV although recurrence may arise.

![Fig. 6. Before (left) and after (right) epidermal grafting in segmental vitiligo.](image)

In vitiligo lesions with leukotrichia present, the possibility of repigmentation may be minimal or absent because the loss of hair melanocytes is usually permanent, and repigmentation may not occur even with medical treatment. We found that the majority of white hairs in SV may contribute to the lack of response to medical treatment and require surgical treatment such as epidermal grafting.

Table 2. Treatment Guidelines for Segmental Vitiligo

Based on previous reports and our experiences, we recently proposed a set of treatment guidelines in SV. Treatments such as topical corticosteroids and topical calcineurin inhibitors, as well as phototherapy, including NB-UVB and targeted phototherapy (e.g., excimer laser) are helpful for SV. Available data suggests that combination topical treatment and phototherapy is more efficacious in SV than any type of monotherapy. In addition, disease duration in SV is very important to consider to gauge response to medical treatment. Thus, as first-line therapy, we recommend the combination of topical treatment and phototherapy to be initiated as early as possible. However, our experience suggests that phototherapy is not helpful in SV patients with the majority of hairs in lesional...
skin being white. Therefore, in these cases, we recommend first-line treatment be surgery in order to avoid delay as well as unnecessary and inefficacious treatment. These guidelines will contribute to future definitive treatment guidelines for SV (Table 2).
