Venous Thromboembolism in Bariatric Surgery

Eleni Zachari, Eleni Sioka, George Tzovaras and Dimitris Zacharoulis

Department of Surgery, University Hospital of Larissa
Greece

1. Introduction

Deep venous thrombosis (DVT) and pulmonary embolism (PE) constitute clinical presentations of the same vascular disease, known as venous thromboembolism (VTE). VTE is responsible for hospitalization of >250000 Americans annually. It is associated with high morbidity and mortality and represents a primary cause of preventable death. There is strong evidence that obesity is an independent risk factor for DVT and PE. Bariatric surgery is proven to be an effective means in the therapy of morbid obesity and its related comorbidities, thus its prevalence is rapidly increasing. Well established and widely performed procedures include laparoscopic adjustable gastric band (LAGB), Roux-en-Y gastric bypass (RYGBP), biliopancreatic diversion (BPD, with or without duodenal switch) and sleeve gastrectomy (SG). LAGB is a purely restrictive method, while RYGBP and BPD are considered as mainly malabsorptive procedures. SG was performed as a bridge to further by-pass surgery, however nowadays is performed as a single stage procedure. The risk of VTE in patients undergoing elective bariatric surgery is high, attributable to obesity, intraoperating factors and the lack of an established guidance describing optimal VTE prophylaxis. Overall incidence of VTE in this population is reported to be 1-3%. Diagnosis of PE postoperatively in obese patients can be difficult due to physical limitations and consequently may be underdiagnosed. Furthermore, although VTE is usually diagnosed as immediate postoperative complication, PE can occur in nonhospitalized patients, within the first month after surgery, despite pharmacologic prophylaxis.

2. Obesity

The most widely applied tool to diagnose obesity is body mass index (BMI). BMI is defined as weight in kilograms divided by the square of height in meters. World health Organization defines obesity as a BMI ≥ 30. This cutoff was selected because according to epidemiological studies mortality curve increases at this value. Moreover, morbid obesity is defined as BMI ≥ 40.

The prevalence of obesity increases rapidly in both developed and developing countries and is considered as one of the most serious public health problems.

Recent scientific data from long-term studies support the strong association between obesity and type 2 diabetes, hypertension, cardiovascular disease, dyslipidemia, arthritis, gallbladder disease, sleep apnea syndrome and many types of cancer. Furthermore, obesity deteriorates quality of life and induces severe psychological disorders.
3. Bariatric surgery

Bariatric surgery holds an important and well established role in the management of obese and morbid obese patients. Furthermore, it is proved to be the most efficient mode of treatment that provides sustained weight loss in morbidly obese patients. International medical and surgical societies (International Federation for the Surgery of Obesity (IFSO), European Association for Study of Obesity (EASO), European Childhood Obesity Group (ECOG)) created guidelines in order to assure safe and effective clinical practice in the field of bariatric surgery.

3.1 Indications of bariatric surgery

a. Patients from 18-60 years
   - with BMI ≥ 40 kg/m²
   - with BMI 35-40 kg/m² and with co-morbidity which weight loss is expected to improve (metabolic disorders, cardio-respiratory disease, severe joint disease, obesity-induced severe psychological problems)

To be candidates for surgical management, patients must have failed to lose weight or to maintain a substantial weight-loss following conservative treatment.

Bariatric surgery is indicated in patients who managed to lose weight prior to scheduled surgery and have reach a BMI below the required for surgery.

b. Patients aged above 60

In these patients the primary objective is to improve quality of life. Benefits should be contemplated with potential risks, thus indications for surgery should be individualized.

3.2 Contraindications of bariatric surgery

- Absence of effort to lose weight following an appropriate non-surgical medical program.
- Psychotic disorders, severe depression, personality disorders.
- Alcohol abuse and/or drug dependencies.
- Life-threatening diseases (in a short term).
- Patients who are unable to care for themselves or to participate and conform to the required long-term medical follow-up.
- Patients in very high or unacceptable anaesthetic risk.

3.3 Bariatric surgery techniques

Nowadays a variety of surgical procedures is available for the surgical treatment of obesity. Furthermore, although primary objective of bariatric surgery is the weight loss, significant long-term amelioration or total remission of co-morbidities has been established. Bariatric surgery procedures modify the gastrointestinal track in order to reduce its volume and/or its absorptive function.

Restrictive procedures induce volume limitation and include laparoscopic adjustable gastric band (LAGB), vertical banded gastroplasty (VBG), laparoscopic sleeve gastrectomy (LSG), gastric bypass (GBP).

Malabsorptive procedures induce limited absorption of nutrients and include biliopancreatic diversion with (BPD-DS) or without duodenal switch (BPD).

Roux-en-Y gastric bypass (RYGBP), open or laparoscopic, encompasses characteristics of both types of procedures, as it provides restriction and mild- malabsorption.
4. Venous thromboembolism

4.1 Predisposing factors to venous thromboembolism in bariatric surgery
Morbid (BMI>50) and truncal obesity are identified as major predisposing factors for VTE. Sedentary lifestyle, increased abdominal pressure and excessive weight resting on the inferior vena cava drainage attribute to the increased risk. Additional risk factors include advanced age, history of previous VTE, immobilization, venous insufficiency and stasis, smoking, estrogen-containing oral contraceptives and hormone replacement therapy, hypercoaguable state, hypoventilation syndrome and anastomotic leakage. According to current literature, obesity interferes in intrinsic and extrinsic coagulation pathways, as well as in the anticoagulant mechanism, leading to a hypercoagulating state. Plasma concentration of fibrogen, von Willebrand, t-PA, PAI-1 and factor VII are significantly elevated in obese patients, while platelet aggregation is promoted due to leptin. There is evidence that treatment of morbid obesity can reverse partially some of the above abnormalities, as weight loss is associated with significant reduction in fibrogen, t-PA, PAI-1 and improvement of deficiency of antithrombin III. Perioperative factors contributing to VTE include extend of surgical trauma, operative duration, length of postoperative immobilization and the use of general versus regional anesthesia. The risk of developing VTE depends on the type of major abdominal surgical procedure. Mukherjee et al. reported lower incidence of VTE among bariatric surgery patients (0.35%), while VTE rates were higher in patients undergoing nephrectomy, hepatectomy, colorectal resection, splenectomy, gastrectomy, pancreatectomy and esophagectomy. This lower rate may reflect strict adherence of bariatric surgeons to VTE prophylaxis guidelines relative to other surgical specialties. More specifically, in laparoscopic bariatric surgery, reverse Trendelenburg position and pneumoperitoneum are associated with venous stasis of lower extremity and impaired venous return due to the compression of iliac veins and inferior vena cava. Furthermore several studies show the development of a hypercoagulable state during laparoscopy. Conversely, the risk of VTE during laparoscopy could be compensated by lower degree of surgical injury, early mobilization and reduced postoperative acute-phase response. Podnos et al. in a review of 3464 cases of GBP demonstrated that although the difference was not statistically significant, the incidence of PE was lower in laparoscopic group rather than the open group. In absence of randomized controlled studies, the evidence remains inconclusive as to the relative risk of VTE after laparoscopic bariatric surgery.

4.2 Prophylaxis of venous thromboembolism in bariatric surgery

4.2.1 Mechanical prophylaxis
Mechanical modalities include graduated compression stockings, intermittent pneumatic compression devices (IPC) and venous foot pump. Perioperative use of the above devices and early mobilization of patients reduce the risk of VTE by increasing venous outflow and preventing venous stasis. Remarkable advantage of mechanical prophylaxis is lack of interference in the coagulation path, which renders it safe for patients in high risk for bleeding. Limitations of the use of mechanical devices are skin irritation and poor compliance.

4.2.2 Pharmacological prophylaxis
Unfractionated heparin (UFH) and low molecular weight heparins (LMWH) are effective in the prophylaxis of VTE in surgical patients. An initial dose of 5000 units UFH is
administered subcutaneous preoperatively and repeated doses every 8 or 12 hours are required. On the contrary, LMWH shows improved pharmacological characteristics, as it requires a single dose per day, has lower degree of plasma protein binding, longer half-life and an enhanced bioavailability. Contraindications in anticoagulation agents are allergy, heparin-induced thrombocytopenia, coagulation disorders, active bleeding or patient at high risk of bleeding.

There is no consensus in literature considering the optimal regimen, dosage, and duration or application mode for VTE preventions in bariatric surgery patients. Furthermore, there is a paucity of data confirming the scaling of dosage according to body weight and renal function. Several authors support low rate of VTE when weight-adapted dosages are administered, while others suggest that there is no significant difference. American College of Chest Physicians recommend the administration of LMWH, UFH 3 times daily, fondaparinux or the combination of one of these pharmacologic method with optimally used IPC (Grade 1C). Although according to recommendations administrated doses should be higher than those for nonobese patients (Grade 2C), adjusting doses according to BMI remain debatable. Current statement of American Society for Metabolic and Bariatric Surgery suggests the use of both mechanical and pharmacological prophylaxis in bariatric patients, without providing further adaptation guidance. Data on compliance of bariatric surgeons with the above guidelines are inconsistent, however treating high-risk bariatric patients seems to have a positive effect in adherence. Wu et al reported that 95% of bariatric surgeon comply with guidelines, while ENDORESE trial proved that only 58,5% of all surgical patients in risk for VTE receive prophylaxis.

4.2.3 The role of inferior vena cava filters
The prophylactic use of inferior vena cava filters (IVCF) remains controversial. Although recent studies report lower incidence of DVT and PE, other suggest that IVCF may reduce the rate of PE, but increase the incidence of DVT. Risk and complications deriving from the implantation of such a device should not be underestimated. Inferior Vena Cava, filter breakage, caval perforation, insertion site hematoma and infection have been reported. Based on the above, American Society of Hematology stated that the evidence to support the efficacy of IVCF in bariatric surgery is insufficient (Grade 2C recommendation against their use).

4.3 Diagnosis of venous thromboembolism
4.3.1 Clinical findings
Presenting symptoms of VTE are rather non-specific (dyspnea, chest pain, tachypnea), rendering the clinical diagnosis difficult. The key to early detection of VTE in bariatric patients is the high degree of vigilance for clinical features of DVT or PE. Physical examination may reveal increased respiratory rate, rales, wheeze, pleural friction rub, cyanosis, tachycardia, loud second heart sound, sings of DVT (oedema, redness, Homan’s sign- pain on passive dorsiflexion of the ankle) and temperature above 38,5°C. Syncope and severe hypotension when present should be considered as signs of hemodynamic compromise.

In obese patients typical clinical findings of DVT or PE can be underestimated, as some of them (edema of lower extremity, tachycardia, dyspnea, tachypnea) pre-exist, due to obesity related co-morbidities, such as cardiac or respiratory failure, varicose veins, obesity related hypoventilation syndrome.
Clinical prediction rules were established in order to overcome the above limitations and provide effective risk stratification of VTE. Wells Score and Revised Geneva Score assess the clinical probability of VTE based on patient’s risk factors and clinical findings.

4.3.2 Laboratory findings
The role of arterial blood gas (ABG) in the diagnosis of VTE is rather limited. Respiratory alkalosis and hypoxemia constitute common but non-specific findings and although their presence should raise suspicion, cannot be used solely for the confirmation of the diagnosis. D-dimers blood test detects a fibrin degradation product and has a high negative predictive value. In bariatric patients has limited value only to exclude VTE, as recent surgery, inflammation and trauma can induce false positive readings.

4.3.3 Imaging studies
Several diagnostic imaging studies can be performed in bariatric population, although limitations occur. Electrocardiogram (ECG) in acute pulmonary embolism can reveal sinus tachycardia, ST segment depression and signs of right ventricular strain (more commonly incomplete right bundle branch block). Echocardiogram may detect right ventricular dysfunction. The high prevalence of cardiovascular diseases (coronary heart disease, left ventricular hypertrophy, atrial fibrillation, arrhythmias) in obese patients renders ECG and echocardiogram diagnostic tools of limited value. Chest radiograph in acute pulmonary embolism may appear normal, while rarely, infiltrates, pleural effusion, atelectasis may be present. Consequently, chest radiograph is more useful in the exclusion of other pathological entities (pneumonia, pneumothorax) that may present with the same clinical picture with pulmonary embolism. In the detection of DVT, Duplex Doppler Ultrasound remains the standard noninvasive examination for the visualization of thrombus, although when performed in obese patients may have reduced accuracy. Chest Spiral CT has recently replaced pulmonary angiography and is now considered as the gold standard in the diagnosis of PE. However, special equipment must be available for morbidly obese patient, given the weight limitation of the conventional ones.

5. Differential diagnosis
Pathological entities that present with the same clinical features and sings as venous thromboembolism and should be part of the differential diagnosis are: pneumonia, pleural effusion, pneumothorax, congestive heart failure, and cardiac ischemia, exacerbation of chronic obstructive pulmonary disease, asthma and pulmonary edema. Furthermore, differential diagnosis of PE after bariatric surgery should include anastomotic leakage, which may also present with tachycardia, fever, chest pain and respiratory insufficiency. An upper gastrointestinal study or surgical intervention may be necessary in order to exclude such a complication.

6. Treatment of venous thromboembolism
European Society of Cardiology guidelines and American Heart Association statement provide evidence-based therapeutic strategies of VTE. Hemodynamic and respiratory
support is vital in patients presenting with PE and right ventricle dysfunction. Standard treatment remains the administration of UFH, LMWH and fondaparinux with the considerations mentioned in the prophylactic use of these agents. Data confirming the safety of weight-based dosage of LMWH are insufficient. Performance of thrombolysis, surgical pulmonary embolectomy, percutaneous catheter embolectomy and IVCF should be guided by evidence-based indications. In the absence of nationwide established guidelines standardized to this special surgical population, potential risk of all the above pharmacological and mechanical means should be taken into account when treating bariatric patients.

7. References

Pulmonary embolism is a serious, potentially life-threatening cardiopulmonary disease that occurs due to partial or total obstruction of the pulmonary arterial bed. Recently, new improvement occurred in the diagnosis and treatment of the disease. The aim of this disease is to re-review pulmonary embolism in the light of new developments. In this book, in addition to risk factors causing pulmonary embolus, a guide for systematic approaches to lead the risk stratification for decision making is also presented. In order to provide a maximum length of active life and continuation of functional abilities as the aim of new interventional gerontology, the risk factors causing pulmonary embolus in elderly individuals are evaluated, and the approach to prevention and treatment are defined. The risk of the development of deep vein thrombosis and pulmonary embolism, combined with obesity due to immobility, the disease of this era, irregular and excessive eating, and treatment management are highlighted. Non-thrombotic pulmonary emboli are also covered and an attempt is made to constitute an awareness of this picture that can change the treatment and prognosis of the disease to a considerable extent. In addition to the pathophysiological definition of pulmonary embolus, the priority goal of quick and definitive diagnosis is emphasized, and diagnostic strategies are discussed in the book. A numerical analysis of the vena cava filters, which is a current approach to prevent pulmonary emboli recurrences, is presented in the last chapter.
