India

1. Introduction

In recent years the number of cosmetic procedures is continuously increasing. Cosmetic procedure/surgery is an elective procedure. It is not an emergency. Hence not only final result but the overall comfort and satisfaction of the patient are equally important. Majority of the procedures are carried out under local anesthesia; so thorough knowledge of local anesthetic agents, types, techniques and their side effects becomes very much important for the aesthetic physicians.

1.1 Learning objectives

At the end of reading of this chapter, reader should be able to understand the scope of various types of local anesthesia in his aesthetic practice, able to choose appropriate local anesthesia according to indication, able to do modification in various techniques according to the demand of situation to give pleasant and comfortable experience to patient during the aesthetic procedure while keeping in mind the possible adverse effects of the anesthesia.

1.2 Mechanism of local anesthetic activity

Studies have shown that local anesthetics inhibit depolarization of the nerve by interfering with the influx of Na⁺ ions. Although the exact mechanism of local anesthetic action is not known, several theories postulate that anesthetics diffuse across the neural membrane and somehow alter the activity of the Na⁺ channel. Local anesthetics are thought to stabilize the membrane at resting potential, increase the threshold for electrical excitation, and reduce the propagation of an excitatory impulse, thereby blocking nerve conduction.¹

The sensation of pain is carried via small unmyelinated nerve fibers (C fibers). These fibers are more sensitive to the actions of local anesthetics as compared to larger nerve fibers that carry other sensations. Consequently patients may be able to feel sensations such as pressure and vibration, while being insensitive to pain.²

1.3 Classification of local anesthetics

Local anesthetics possess a basic chemical structure that gives it amphipathic characteristics. Its structure can be divided into three distinct parts: an aromatic portion (lipophilic),
intermediate chain, and amine group (hydrophilic). The intermediate chain connects the aromatic group to the amine group. It is also the basis of local anesthetic classification as either esters or amides (Table 1).

Ester anesthetics are metabolized via the plasma enzyme, pseudocholinesterase. Hydrolysis is rapid and the by-products are excreted in the urine.

Amide anesthetics are metabolized primarily by the liver. They should be used with caution in patients with liver disease.³

For detailed discussion on pharmacology of local anesthetic agents, kindly refer to the related chapter in this book.

1.4 Combination of Local anesthetics and adrenaline⁵,⁶

Many times local anesthetic is administered along with vasoconstrictor like adrenaline with beneficial results. This combination offers following advantages:

1. Decrease anesthetic absorption and systemic toxicity with improved efficacy and smaller amounts required.
2. Prolonged duration of action (almost doubled), especially with lignocaine and procaine
3. Less bleeding at operative site, especially useful on vascular areas with better visualization of operative field.

Adrenaline may potentially induce adverse effects. Therefore its use must be carefully considered in patients with heart disease and those patients concomitantly taking β-blockers.⁷

Table 2. Adverse Effects of Lidocaine with Epinephrine

2. Types of local anesthesia for cosmetic procedures

2.1 Topical anesthesia

Topical anesthesia is the surface application of a LA to the skin or mucous membrane by means of a spray, spreading of an ointment,). Lidocaine 2% jelly, EMLA cream, or iontophoresis of lidocaine can allow one to perform simple procedures such as shave biopsies, electro-cauterization of epidermal growths or superficial laser surgery. Topical
anesthetics can also provide surface anesthesia to permit painless insertion of a needle, especially in children, and on painful areas such as the nose, lips and genitalia.

2.1.1 Mucosal agents

Topical anesthetics agents are useful on mucosal surfaces include cocaine 4%, benzocaine 5-20%, tetracaine 0.5% and lidocaine 2-5% (jelly, ointment), lidocaine 10% aerosol etc.

2.1.2 Cutaneous agents

Creams: for producing an anesthesia on intact skin, creams of lidocaine (30%) or EMLA – eutectic mixture of local anesthetics have to be applied for variable period of time (30min to 2 hours) according to the composition of the EMLA. This EMLA has to be applied under occlusion for its optimum effect. The list of commonly available topical anesthetic is given in Table 3.

Special delivery techniques for topical anesthesia

- Iontophoresis
  
The introduction of various ions into the skin through the use of electricity has been increasingly used to provide pain relief in outpatient procedures. It uses an electric current to overcome some of the barriers of the skin and assist the penetration through the movement of ions into the skin via sweat glands, hair follicles and sebaceous glands.
  
  Iontophoresis can be used to deliver chemicals to both superficial and deeper layers of the skin.

  Advantages are
  1. It avoids pain associated with injections.
  2. It prevents the variation in absorption seen with oral medications
  3. It bypasses first-pass elimination
  4. Drugs with shorter half life can be delivered directly to the tissue

  Disadvantages are
  1. Discomfort and erythema at the site of iontophoresis secondary to pH changes
  2. There is also potential of skin irritation and burn

- Laser assisted delivery of Topical anesthetics:
  
  A research in 2003 indicates that a single pass of the Er:YAG laser (wave length 2940 nm) enhanced the absorption and penetration of lidocaine by disrupting the stratum corneum.

  Although this technique may not be adequate for invasive procedures, it may minimize pain and discomfort for more superficial cutaneous procedure, such as hypodermic needle insertion. This is a well known fact that reapplication of topical anesthetic after first pass of ablative lasers produce quicker and deeper anesthesia.

  Interest in laser assisted drug delivery was reemerged after advent of fractional lasers. Narrow but deep vertical channels of ablation into skin created by fractional CO2 laser were used to successfully deliver a drug, methyl 5-aminolevulinate (MAL) to a uniform depth into skin. The absorption was uniform and full thickness indicating drug delivery from lateral walls of the tunnel. Currently trials are under progress to use this method to deliver local anesthetic agent to skin.

• Needle-less Dermajet
  This is a needleless pressure injection syringe for the intradermal infiltration of drugs in a soluble state. This technique achieves almost painless tissue infiltration with a high velocity microspray in single or multiple doses of 0.1 cc. to a depth of 2 to 5 mm. without actual contact with the site of injection. A fine jet emitted under great pressure punctures the tissue without coring, with a minimum amount of trauma, raising instantaneously a well-defined pinpoint wheal. Besides giving local anesthesia this mode of drug delivery is useful in intralesional steroid injection in case of keloid and hypertrophic scar, in mass vaccinations etc.

• Microporation
  Iontophoresis applies a small low voltage (typically 10 V or less) continuous constant current (typically 0.5 mA/cm² or less) to push a charged drug into skin or other tissue. In contrast, electroporation applies a high voltage (typically, >100 V) pulse for a very short (μs-ms) duration to permeabilize the skin. Low frequency ultrasound is also used as ‘sonoporation’.

2.2 Infiltration anesthesia

This is the most commonly used method of anesthetizing the skin. It consists of injecting the anesthetic agent into the tissue to be cut. The injection may be intradermal, when the anesthesia is almost immediate, or into the subcutaneous tissue, when the anesthesia is usually delayed and has a shorter duration. However, an intradermal injection is more painful. The pain of a LA injection into the skin can be reduced by adding freshly prepared sodium bicarbonate (8.4%) solution to the LA solution in a 1:10 dilution. Local pain can also be reduced by injecting the drug slowly, while pinching the neighboring skin to distract the patient. The infiltration may distort the operative site; this can be minimized by gentle massage after the injection.

2.3 Field blocks

A field or ring block is a variation of infiltration anesthesia. The LA agent is placed around the operative site, anesthetizing the nerve fibers leaving from the area. A ring block is useful when direct needle entry into a lesion such as a cyst is not desirable. The LA has to be placed in both superficial and deep planes. Start injecting from proximal to distal end. This also limits the amount of LA needed to anesthetize the operative site. This is a particular advantage when a large area has to be anesthetized.

2.4 Peripheral nerve blocks

A nerve block involves placing the local anesthetic solution in a specific location at or around the main nerve trunk that will effectively depolarize that nerve and obtund sensation in the area of sensory distribution of that particular nerve. In dermatological surgery, the commonly employed nerve blocks are for the digits and for the central face, because both areas are painful to anesthetize using local infiltration. Peripheral nerve blocks are difficult to perform and complications include laceration of the nerve, intravascular injection of LA and hematoma formation may occur.
Advantages of nerve blocks include the fact that a single accurately placed injection can obtund large areas of sensation without tissue distortion at operative site.

Disadvantages of peripheral nerve blocks include the sensation of numbness in areas other than the operative site and the lack of hemostasis at the operative site from the vasoconstrictor component of the local anesthetic injection.

Since many nerves are accompanied by corresponding veins and arteries, pre-injection aspiration should always be performed to prevent intra vascular injection. Use of local anesthetics with vasoconstrictors will prolong anesthesia.

3. Sensory nerves and respective dermatomes of face and their block

3.1 Fig 1a and 1b Sensory innervations of face and neck area

Trigeminal nerve

Often referred to as "the great sensory nerve of the head and neck", the trigeminal nerve is named for its three major sensory branches. The ophthalmic nerve (V1), maxillary nerve (V2), and mandibular nerve (V3) are literally ‘three twins’ (trigeminal) carrying sensory information of light touch, temperature, pain, and proprioception from the face and scalp to brainstem. The main branches of the trigeminal nerve supply sensation to the well defined and consistent facial areas.

Fig. 1a.
3.2 Anatomic arrangement of facial foramina

Successful nerve block anesthesia is largely dependent upon knowing the position of the nerve foramina. The surgeon can take advantage of the alignment of the major facial foramina as they relate to a vertical line through the mid pupillary line with the eye in the primary position of natural forward gaze.

3.3 Common nerve blocks

1. Supraorbital nerve
   The supraorbital nerve exits through a notch (in some case a foramen) on the superior orbital rim approximately 27 mm lateral to the glabellar midline. This supraorbital notch is readily palpable in most patients. After existing the notch or foramen, the nerve traverses the corrugator supercilii muscles and branches into a medical and lateral portion. The lateral branches supply the lateral forehead and the medial branches supply the scalp.

2. Supratrochlear nerve and Supraorbital
   The supratrochlear nerve exits a foramen approximately 17 mm from the glabellar midline and supplies sensation to the middle portion of the forehead. The infratrochlear nerve exits a foramen below the trochlea and provided sensation to the medial upper eyelid, canthus, medial nasal skin, conjunctiva, and lateral lacrimal apparatus.

When injecting this area it is prudent to always use the nondominant hand to palpate the orbital rim to ensure that the needle tip is exterior to the bony orbital margin. To anesthetize this area, the supratrochlear nerve is measured 17 mm from the glabellar midline and 1-2 mL of local anesthetic is injected. The supraorbital nerve is blocked by palpating the notch (and/or measuring 27 mm from the glabellar midline) and injecting 1-2 mL of local
anesthetic solution. The infra trochlear nerve is blocked by injecting 1-2 mL of local anesthetic solution at the junction of the orbit and the nasal bones.

3.4 Infraorbital nerve block

This block is one of the most commonly utilized facial blocks in order to anesthetize the upper lip and upper nasolabial fold for injection of fillers. Obviously, a bilateral block must be performed to achieve anesthesia on both sides of the lip.

The Infraorbital nerve exits the Infraorbital foramen 4-7 mm below the orbital rim in an imaginary line dropped from the midpupillary midline. The anterior superior alveolar nerve branches from the Infraorbital nerve before it exits the foramen, and thus some patients will manifest anesthesia of the anterior teeth and gingival if the branching is closed to the foramen. Areas anesthetized include the lateral nose, anterior cheek, lower eyelid, and upper lip on the injected side. This nerve can be blocked by intraoral or extraoral routes.

To perform an Infraorbital nerve block from an **intraoral** approach, (fig 3) topical anesthesia is placed on the oral mucosa at the vestibular sulcus just under the canine fossa (between the canine and first premolar tooth) and left for several minutes. The lip is then elevated and a ½ inch 30 gauge needle is inserted in the sulcus and directed superiorly towards the Infraorbital foramen. Bending the needle at 45 degree angle upward can facilitate the needle insertion. The needle needs only to approach the vast branching around the foramen to be effective. It is important to use the other hand to palpate the inferior orbital rim to avoid injecting superiorly the orbit. 2-4 mL of 2% lidocaine is injected in this area for the Infraorbital block and the palpating finger can feel the local anesthetic bolus below the Infraorbital rim, confirming the correct area of placement.

The Infraorbital nerve can also be very easily blocked by the **transcutaneous facial approach** and may be the preferred route in dental phobic patients. (fig 4). A 32 gauge ½ inch needle is used and is placed through the skin and aimed at the foramen in a perpendicular direction. Between 2 and 4 mL of local anesthetic solution is injected at or close to the foramen.
the other hand must constantly palpate the inferior orbital rim to prevent inadvertent injection into the orbit. Care must be taken in this approach to avoid superficial vessels that may cause noticeable bruising.

A successful Infraorbital nerve block will anesthetize the Infraorbital cheek, the lower palpebral area, the lateral nasal area, and superior labial regions as shown in figure.

3.5 Zygomaticotemporal nerve block

Two uncommon facial local anesthetic blocks are the zygomaticotemporal and zygomaticofacial nerves. This may assist the injection of fillers in facial rhytides on the lateral temporal and lateral canthal areas or in the malar areas. These nerves represent the terminal
branches of the zygomatic nerve. The zygomaticotemporal nerve emerges through a foramen located on the anterior wall of the temporal fossa. This foramen is actually behind the lateral orbital rim posterior to the zygoma at the approximate level of the lateral canthus.

To orient for this injection it is necessary to palpate the lateral orbital rim at the level of the frontozygomatic suture (which is frequently palpable). With the index finger in the depression of the posterior lateral aspect of the lateral orbital rim (in inferior and posterior to the frontozygomatic suture), the operator places the needle just behind the palpating finger (which is about 1 cm posterior to the frontozygomatic suture). The needle is then ‘walked’ down the concave posterior wall of the lateral orbital rim to approximate level of the lateral canthus. After aspirating, 1-2mL of 2% lidocaine is injected in this area with a slight pumping action to ensure deposition of the local anesthetic solution at or about the foramen. Again, it is important to hug the back concave wall of the lateral orbital rim with the needle when injecting.

Blocking the zygomaticotemporal nerve causes anesthesia in the area superior to the nerve, including lateral orbital rim and the skin of the temple from above the zygomatic arch to the temporal fusion line.

3.6 Zygomaticofacial nerve block

The zygomaticofacial nerve exits through a foramen (or foramina in some patients) in the inferior lateral portion of the orbital rim at the zygoma. If the surgeon palpates the junction of the inferior lateral portion of the lateral orbital rim, the nerve emerges several millimeters lateral to this point. By palpating this area and injecting just lateral to the finger, this nerve is successfully blocked with 1-2mL of local anesthetic. Blocking this nerve will result in anesthesia of a triangular area from the lateral canthus and the malar region along the zygomatic arch and some skin inferior to this area.

3.7 Mental nerve block

The mental nerve exits the mental foramen on the hemimandible at the base of the root of the second premolar (many patients may be missing a premolar due to orthodontic extraction). The mental foramen is on average 11 mm inferior to the gum line. There is variability with this foramen, but by injecting 2-4 mL of local anesthetic solution about 10 mm inferior to gum line or 15 mm inferior to top of the crown of the second premolar tooth the block is usually successful. In a patient without teeth, the foramen is often times located much higher on the jaw and can sometimes be palpated. This block is performed more superiorly in the denture patient. As stated earlier, the foramen does not need to be entered as a sufficient volume of local anesthetic solution in the general area will be effective. By placing traction on the lip and pulling it away from the jaw, the labial branches of the mental nerve can be seen traversing through the thin mucosa in some patients. The mental nerve gives off labial branches to the lip and chin.

Alternatively, the mental nerve may be blocked through the skin of the cheek with a facial approach, aiming for the same target.

When anesthetized the distribution of numbness will be the unilateral lower lip to the midline and laterally to the mentolabial fold, and in some patients the anterior chin and cheek depending on the individual furcating anatomy of that patient’s nerve.
As mentioned earlier, sometimes patients may perceive pain despite bilateral nerve block in the upper or lower lips. When injecting fillers in the lower lip and bilateral mental nerve blocks are not totally effective, a supplemental infiltration of several milliliters of local anesthetics region of the mandibular labial frenulum can assist the block.

**Anesthesia for aesthetic lip augmentation**

Although in theory a bilateral Infraorbital block should anesthetize the entire upper lip, some patients may still perceive pain for various anatomic (or sometimes psychological) reasons. It is recommended that the injection of 1.0mL of local anesthetic solution in the maxillary labial frenum. This can also be performed in the lower lip labial frenum area to augment bilateral mental blocks.

### 3.8 Digital nerve block

This is commonly performed nerve block by dermatosurgeons for nail surgeries, acral vitiligo correction, multiple verrucae on fingers, etc.

Each digit is innervated by two dorsal and two ventral branches of nerve as follows:

- **Fingers** – Radial and ulnar nerves on dorsal surface.  
  Median and ulnar nerve on palmar surface
- **Toes** – Peroneal nerve on dorsal surface.  
  Tibial nerve on plantar surface.  
  Rarely, Saphenous nerve on dorsal aspect of great toe.

Two methods exist for achieving a digital block viz. ring block and metacarpal/metatarsal head technique (anesthetizing the nerves before they enter the digits). Ring block is more commonly used in day to day practice.

#### Ring block

The 0.5-1 mL of local anesthetic (without adrenaline) is injected with the help of 26 gauge ½ inch needle at the dorsolateral margin of the desired digit at the level of webspace. The needle is advanced further across the dorsal aspect of the digit and the anesthetic solution injected in superficial (subcutaneous) and then deep plane (close to the bone). It is then withdrawn up to the insertion point and rerouted along the palmar surface in a similar manner and after depositing 0.5-1mL, the needle is completely removed. The hand is turned over and needle inserted at the palmar medial surface at level of webspace of the same digit. It is pushed across laterally and solution injected, withdrawn to insertion point, redirected medially to complete the block.

#### Metacarpal/metatarsal head technique

The needle is introduced in the space between the heads of the metacarpals / metatarsals, proximal to the webspace and perpendicular to skin. It is advanced in a similar direction towards the palmar / plantar aspect of the hand/foot, till it reaches the subcutaneous level here.

The local anesthetic solution is then injected thus blocking the digital nerves at the level before they enter the digit. The needle is withdrawn and the procedure repeated on the other side of the respective metacarpal/metatarsal head.
Since the blood supply to digits is by terminal arteries, adrenaline should not be mixed with local anesthetic. The volume injected to produce block should not exceed 8mL as larger volume can produce mechanical compression on vasculature results in ischemia and digital necrosis.

Sometimes, the anesthesia achieved is unsatisfactory; the reason for this could be failure to infiltrate the local anesthetic close to bone, where nerve lies; or failure to anesthetize adequate length of the nerve. Both causes can be avoided by using higher concentration solutions.

Reducing the pain of local anesthesia

The introduction of needle and infiltration of anesthetic are many times very painful and may provoke intense anxiety and can lead to an unpleasant surgical experience for the patient.

The pain experienced during the administration of local anesthetics may be attributed to the needle puncture of the skin, tissue irritation from the solution, and tissue distention from the infiltration.

To minimize pain physician should be reassuring, distracting patients through conversation or slightly vibrating the skin may decrease their perception of pain. For extremely anxious patients, mild sedation with a benzodiazepine may be helpful.

a. Reducing the needle prick pain
   - Explanation of procedure,
   - Use of mild sedation
   - Use of topical anesthetic cream can be helpful to minimize pain.
   - Use of small diameter needle can be less painful compare to larger diameter needle.
   - Longer needle should be used when anesthetizing large areas to avoid multiple pricks
   - Use of long acting local anesthetic helps to avoid repeated pricks if procedure is more time taking.
   - Slow introduction of needle, introduction of needle through accentuated pore (on face), reinsert needle in an area already anesthetized are other way to reduce the pain associated with needle prick.

b. Reducing the pain associated with tissue distension
   - Slow injection of anesthetic solution, only required amount to be injected, inject into subcutaneous fat, use of field block, being injecting the drug proximally and advanced distally (produce anesthesia distal to needle tip reducing the pain of advancing injection needle).

c. Reducing the pain due to tissue irritation
   - The tissue irritation from local anesthetics is primarily due to the acidity of the anesthetic solution. The anesthetics are acidified to increase their solubility, as well as their chemical stability. To decrease irritation produced by local anesthetics, the solution may be buffered through several means:
     - Mix lidocaine with adrenaline with plain lidocaine in equal part.
     - Mixed plain lidocaine (10 mL) with adrenaline (0.1mL). The subsequent solution is lidocaine with adrenaline, but at same pH as plain lidocaine.
     - Add sodium bicarbonate to the anesthetic solution (lidocaine with adrenaline: sodium bicarbonate in 10:1) to increase the pH of local anesthetics to near tissue fluid levels.
4. Tumescent anesthesia

This is a technique of local anesthesia which involves the subcutaneous injection of large volumes of dilute LA in combination with adrenaline and other agents is used for dermabrasion, skin grafting, rhinophyma correction, liposuction and hair transplant procedures, most common being liposuction. The plasma concentrations may peak more than 8-12 hours after infusion. Clinicians are advised to exercise great caution in administering additional local anesthesia by infiltration or other routes for at least 12-18 hours following the use of this technique.

4.1 Tumescent fluid – Composition

- Normal Saline 1000 cc
- Lidocaine (2%) 50 cc
- Adrenaline (1:1000) 1 cc
- Sodium bicarbonate (8.4%) 10 cc
- Effective concentration of lidocaine – 0.1%

(Safe up to 55 mg/kg, according to the American Academy of Dermatology guidelines of care for liposuction.)

4.2 Advantages

1. The injection is almost painless as it is placed subcutaneously, where the lax tissue is easily distensible
2. It pushes up or stretches the skin and the area to be operated and provides a cushioning effect to deeper structures, so less chance of their damage.
3. Provides very good hemostasis due to large volume of anesthetic compresses the subcutaneous vasculature.
4. It causes hydrodissection at subcutaneous layer and provide safer plane for dissection like in donor strip harvesting in hair transplantation, due to volume of anesthetic injected and also helps to preserve the dermal tissue architecture since injection is placed at deeper level.
5. Smaller quantity of actual anesthetic agent is required for desire action which reduces the possibility of systemic side effects.
6. Prolonged area of several hours’ duration occurs as a result of a reservoir effect of local anesthetic.
7. The addition of adrenaline increases the duration of action, while sodium bicarbonate helps to adjust the pH of the formulation to a level very close to that of the tissue fluid, which reduces the tissue irritation and pain during the injection of Tumescence anesthesia.
8. Elimination of general anesthesia, hospital operating facilities, and hospital overnight stays also result in a favorable impact on costs when this technique is employed.

4.3 Disadvantages

1. Since the prepared solution is placed subcutaneously, there is more diffusion in this highly distensible compartment and faster absorption through this vascular tissue.
2. Onset of anesthetic action takes 10-15 minutes due to time taken to penetrate the dermal nerves from deeper plane.
4.4 Calculation of maximal tumescent technique lidocaine dose for 70 kg liposuction patient

\[
(55 \text{mg/kg})(80 \text{kg}) = 4400 \text{ mg}
\]

If 0.1% lidocaine solution is used, then

\[
(4400 \text{ mg}) / (1 \text{mg/L}) = 4.400 \text{ L}
\]

4400 mL of 0.1% solution

4.5 Tumescence infiltration technique

Tumescent fluid is infiltrated in tissue either by a syringe with needle or by infusion canula.

Skin is gently numbed by infiltration of same tumescent solution at places of anticipated adits. Small access openings are made to insert infusion canula attached either to a lure locked syringe or infusion pump. Tumescent fluid in infiltrated till the skin shows pallor. Rate of infusion should be slow to avoid discomfort due to rapid stretching of skin.

Tumescence solutions: concentration, volume, used for various body areas\textsuperscript{21}

Discomfort during the infusion may be due to\textsuperscript{21}

- Too high infusion rate – decrease the rate
- Advancing an infusing cannula too rapidly- consider slower advancement, consider needle infusion, or initiating infusion with needle prior to using infusion cannula

www.intechopen.com
- Skin surface inadequately numbed – re numb the skin.

**Local Anesthesia in Hair Transplantation**

- Anesthesia for strip removal
  - Infiltration with lidocaine 1cm lower than lower incision line
  - Tumescent fluid infiltration
- Anesthesia in frontal (donor) area
  - Nerve blocks for supra-orbital and supratrochlear
  - Tumescent fluid infiltration
- Anesthesia for FUE donor site
  - Field block
  - Tumescent fluid infiltration

5. **Non pharmacological anesthesia**

a. Hypnosis, talkasthesia

Many patients may be benefited just by soothing verbal and tactile reinforcement from doctor as well as family members. This works on principle of hypnosis as a tool to enhance the patient’s tolerance level. The patient is asked to relax and be calm. Sometimes physician can ask the patient to concentrate on breathing – slow steady inspiration and expiration to the count of ‘one-the-three’. – This maneuver helps the majority of the patient to relax and calm. Holding the patient’s hand, with or without gentle stroking, is also a calming procedure.

b. Vibration anesthesia

Vibration has been used for many years to reduce pain in disciplines such as dentistry and physiotherapy, and is now becoming recognized as a simple, safe and effective form of anesthesia in dermatology. Vibration anesthesia can be explained by the ‘gate theory of pain control’ popularized by Melzack and Wall in the 1960s. Noxious nerve impulses evoked by injuries are influenced in the spinal cord by other nerve cells that act like gates, either preventing the impulses from getting through, or facilitating their passage. Without vibratory modulation, noxious impulses are carried through small C fibers uninhibited through a ‘gate’ in the spinal cord that ultimately sends the signal to the brain. When applied simultaneously, vibratory stimulation excites large A fibers, which activates inhibitory interneurons at the gate and mitigates the perception of pain in the brain.

Any vibratory massager can be used to produce the vibratory stimulation. A study has shown that pain sensitivity gradually declines as vibration amplitude increases, but no specific frequency is more effective in interference with nociception. The vibratory massager should be applied approximately 2-3 seconds prior to the injection or laser application and 1-2 cm from the site, and continue throughout the procedure.

c. Cooling

Cooling can be achieved using sprays, cold air, ice, ice packs, and gels. Cooling can reduce the discomfort of many procedures. Both pain and temperature sensation travel in the same nerve pathway. If this nerve pathway is overloaded by the cold sensation, pain is less likely to be felt in the same area.
Refrigerant spray: It is a form of cryoanesthesia, which works on ‘gate theory’ of pain control. It is a spray containing ethyl chloride or dichlorotetrafluoroethane. The refrigerant is sprayed for 2-5 seconds, depending upon the distance from the skin until a white frost is seen and then immediately the short procedure has to be carried out.

5.1 Cooling methods for various lasers

Cooling in laser procedures acts not only as numbing agent but a epidermal protector. Following are various ways to cool epidermis while achieving changes in deeper part of skin.

- Icing before laser
- Cool air flow (Zimmer Cryo)
- DCD spray
- Sapphire tip contact cooling
- Metal tip contact cooling
- Cool gel

5.2 Role of anesthesia in outcome of aesthetic procedure:

Anesthesia in aesthetic procedures has not only a functional role but also has a great psychological impact on perception of the procedure by the patient. Successful anesthesia and analgesia makes the aesthetic procedure a pleasant experience for the patients and encourage them to go for such repeated procedures.

6. Summary

Local anesthesia makes cosmetic procedures not only appealing but cost effective also by making them day care ones. A topical anesthetic cream with occlusion is most common technique of local anesthesia. Field block is achieved by infiltration of LA in and around area to be treated. It is modified to target an innervating nerve trunk by various nerve blocks. Tumescent local anesthesia is a state of art modification of LA to anesthetize a very large volume of tissue for prolonged period without significant adverse effects. Mastering the art and science of local anesthesia is very much essential in successful outcome of aesthetic procedures.

Clinical Use of Local Anesthetics

Local anesthetics are being increasingly applied in different surgeries. Lower side effects of neuroaxial anesthesia, regional anesthesia, and field block, in comparison to general anesthesia (volatile and intravenous agents), are the main reasons why physicians prefer to conduct surgeries under local anesthesia, especially in outpatient and day care surgeries. It is important to emphasize the presence of an anesthesiologist, and vigilant monitoring of the homodynamic parameters, in decreasing a patient's anxiety, exerting other modalities for analgesia and increasing the safety margin in many procedures.
