1. Introduction

Multiple myeloma (MM) or plasma cell myeloma is a neoplastic proliferation of plasma cells that primarily involves the bone marrow but may originate from extramedullary sites [1-4]. Although it is uncommon in veterinary medicine, it has been reported in several species, including cats, dogs and, horses [1,3,5-10]. The frequency of MM in cats is slightly <1% of all malignant neoplasms. Canine MMs account for only 0.3% of all malignancies in dogs. MMs account approximately 2% of all hematopoietic neoplasms in both dogs and cats [4]. Most of the reports in the literature are limited to 1 to 16 case studies [4,11-16]. However, in a recent report regarding the incidence of bone disorders diagnosed in dogs, MM was the second most frequently diagnosed neoplastic condition in canine bone marrow [17].

Similarly, MM is an extremely rare disorder in horses. Ten cases, nine from the literature and a new case, were described by Edwards et al. [1] and only six additional cases have been described lastly [3,6-8,18]. Because of the uncommonly diagnosis of equine MM, the prevalence of this neoplasm is unknown in the horse.

2. Data of the patients with multiple myeloma

MM is generally a disease of older animals, although some reports exist in young animals. In dogs, the average age of diagnosis is between 8 and 12 year-old [9-10,15,19-25]. There is a report of MM in a younger dog, 4-year-old [26]. There is no apparent gender predisposition

in dogs. Further, the largest retrospective study to date (60 dogs) included 30 males and 30 females [27].

The mean age of diagnosis in cats ranges between 12.5 and 14 years, and most of the cats with MM are older than 7 year-old [28,29,4,30,31,32,33,9]. According to the literature, the youngest cat with MM was 1.5 year-old [31]. A myeloma-related disorder has been described for a 19-month-old cat [34]. Males accounted for about 55-56%. The age and gender in dogs and cats with MM are similar to those described in human patients. In a large retrospective study of 1027 people, the average age of diagnosis was 66 years and 59% were men [35].

MM is also a neoplasm of elderly horses, with mean age of 11 years at the moment of the diagnosis [1]. Horses with this condition have ranged in age from three months to 25 years. The youngest animals were a 1.6-year-old Quarter Horse mare [36] and a 3 month-old Quarter Horse colt [37]. Although it was suggested initially that it could be more common in Quarter Horses [1], there are too few reports in equids for statistical interpretation of this data. Both male (geldings and stallions) and female horses are represented equally.

3. Current knowledge of the etiology and predisposing factors of MM in companion animals

Factors associated with the development of MM in companion animals have not been identified. In human patients, exposure to high doses of ionizing radiation has been linked to MM development according to some studies [38-40]. In relation to x-rays, the results of many cohort studies in human beings have been inconsistent, in some cases suggesting that frequent exposure has a negligible effect and in other that it is a significant risk [41-43]. In one report of equine MM, one horse was used regularly for teaching radiology and Pusterla et al. [3] suggested that it might exist an association between exposure to x-rays and neoplastic transformation.

Genetic and hereditary factors may also play a role in MM development [44-45]. Recurrent infections or antigen stimulation have been proposed as predisposing factors, although epidemiological studies have not been confirmed this association [46]. Infections with several virus diseases in human patients appear related to an elevated MM risk, although some data do not support a potentially causal relationship between these infections and MM [46-50]. In cats, a link between MM and virus such as feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) has not been identified, but a diagnosis of the disease among sibling suggests a familiar association [29]. The role of oncogenes, tumor-suppressor genes, cytokines, and their interaction with the bone marrow environment in the etiopathogenesis of the MM are currently being investigated in animal models. Overexpression of cell cycle regulators, such as cyclin D1 and dysregulation of receptor tyrosine kinase have been implicated in the pathogenesis of plasma cell tumors and MM [51]. Progression of B cell lymphoma to MM and of solitary plasma cell tumors to MM in dogs and cats have been reported [52-53].

4. Clinical signs

The infiltration of various organ systems by neoplastic cells, the production of cytokines by the tumor or the bone marrow microenvironment, and the high circulating level of a single type of immunoglobulin lead to a wide array of clinical manifestations. Therefore, the clinical signs of MM vary with the level of plasma cell proliferation, the location and spread of the neoplastic plasma cells, and the nature and extent of the proteinuria [3,4,9-10,15,33,54]. The clinical signs are generally non-specific and include lethargy, renal failure, hemostatic abnormalities, anorexia, diarrhea and vomiting in small animals and weight loss, anorexia, fever, increased susceptibility to infections and limb edema in horses [1,3,8,11,36].

4.1. Increased susceptibility to infections

MM patients are usually immunocompromised and thus highly susceptible to infections [55]. MM associated immunodeficiency is likely a multifaceted phenomenon secondary to decreased concentration of polyclonal immunoglobulin [56], suppression of macrophage-related factors influencing the normal B cell differentiation to plasma cells [57] in response to antigenic stimulation [58], decreased T helper cell function, increased rate of γ -globulin catabolism, neoplastic infiltration of bone marrow resulting in leukopenia [59], dysfunctional and/or decreased numbers of neutrophils, and defective complement activation [3-4].

In cats with MM, the most common infectious processes include periodontitis, chronic recurrent upper respiratory infections and terminal bacteremia [4]. In horses with MM, the most common system affected by infectious disease is the lung, with several cases of severe pneumonia [1,3,37,60].

4.2. Bone pain and skeletal lesions

Bone pain is considered one of the most common presenting complaints in human patients [61-62]. Skeletal abnormalities are commonly recognized in small animals, but uncommon in horses with MM [1,3,63]. Horses frequently had bone lesions, therefore, bone pain might manifest more as a gait abnormality and therefore, it could be misdiagnosed.

The percentage of cats with MM and radiographically-evident skeletal lesions was 58.3% [2,4,13,63-66], similar to the 50-60% occurrence reported for dogs [27,64]. Skeletal lesions can be either solitary (well-circumscribed with areas of osteolysis or punched-out lytic areas) or multiple (generalized osteopenias) [4,27]. Rarely, pathologic fractures are seen. Skeletal lesions are typically identified in bones involved in active hematopoiesis (e.g. ribs, vertebrae, pelvis, and proximal and distal aspects of long bones). Other causes of focal osteolysis are rare in companion animals, but include carcinomas [67], giant cell tumors of bone [68], benign aneurismal bone cysts [69-71] and bone lesions secondary to tumor invasion [70,72-73]. Generalized osteopenias have also been diagnosed radiographically [4]. Demineralization of bone in humans is detected through measurement of bone mineral density, a technique not used routinely in veterinary medicine. Generalized osteopenias is not specific for MM, and may also be seen with nutritional, renal and metabolic disorders [74-77].

4.3. Bleeding disorders

Bleeding is a prominent feature of MM in human beings [78-82]. Clinically, hemorrhages occur in approximately one-third of dogs and one fourth of cats with MM [4,27,29]. In horses, the most common clinical manifestation is epistaxis [1,3,6].

The pathogenesis of bleeding diathesis is likely multifactorial. The M-component may interfere with normal coagulation and lead to hemostatic defects by various mechanism that include inhibition of platelet aggregation and release of platelet factor, adsorption of minor clotting factors, induction of abnormal fibrin polymerization and functional decrease in calcium. In instances where myelophthisis is present due to profound bone marrow infiltration, thrombocytopenia may develop and contribute to hemorrhagic events [24].

4.4. Hyperviscosity syndrome

The hyperviscosity syndrome (HVS) is characterized by clinico-pathologic abnormalities that occur secondarily to increased serum viscosity, which is associated with the M-component. HVS is most commonly associated with immunoglobulin-M macroglobulinemia due to the high molecular weight of IgM [85]. However, it also can occur in presence of IgA, and rarely with IgG [27]. HVS leads to bleeding diathesis, neurological signs (such as seizures, depression, coma), congestive heart failure, renal failure and ophthalmic abnormalities, including tortuous and dilated retinal vessels, retinal hemorrhages and retinal detachment, sludging of blood within small vessels and impaired delivery of nutrients and oxygen to tissues [84].

Approximately 20% of dogs with MM develop this syndrome and it has been reported in cats [4,13,19,23,54,85]. There is a report that measured serum viscosity in a horse with MM [86]. The horse had a serum concentration of globulin of 9.6 g/dl (reference range 3.5-4.5 g/dl) and a relative serum viscosity of 7 (reference range 1.4-1.7). In horses, edema is a common clinical signs in MM [1,3]. The genesis of limb edema is unknown, although blood hyperviscosity may be contributory. Increased vascular permeability has been proposed as a cause of edema accompanying osteosclerosis myeloma in human beings [87].

4.5. Renal disease

Renal disease occurs in approximately 22-50% of dogs and about 30% of cats with MM [4,27]. The pathogenesis of renal disease is commonly multifactorial and several mechanisms have been implicated in human patients [88-89]. In the majority of the cases, renal impairment is caused by the accumulation and precipitation of light chains, which forms casts in the distal tubules, resulting in renal obstructions. In addition, myeloma light chains are also directly toxic on proximal renal tubules, further adding to renal dysfunction [89-90]. Circulating monoclonal light chains are relatively freely filtered through the glomerulus, reaching the proximal tubule, where they are catabolized. Free light chains are endocytosed by proximal tubule cells, through a receptor-mediated process, by binding to the tandem scavenger receptor system cubilin/megalin. Then, they are endocytosed through the clathrin-dependent endosomal/lysosomal pathways and degraded within lysosomes [91-94]. In

MM, excess light chain production overcomes the capacity of the tubular cells to catabolize the free light chains that appear in the tubular fluid of distal nephron segments. Therefore, they form tubular casts with Tamm-Horsfall protein (uromodulin), a glycoprotein-synthesized by the cells in the medullary thick ascending limb of the loop of Henle with affinity for monoclonal light chains. Light chains interact through their complementary determining region with a specific binding site on the Tamm-Horsfall protein and form aggregates and casts that subsequently lead to the tubular obstruction of the distal tubule and the thick ascending loop of Henle [95-97]. Tubular obstruction increases intraluminal pressure, reduces glomerular filtration rate and reduces interstitial blood flow, thus further compromising the renal function [90]). The rates of cast formation increase when light chains increase, although there is considerable diversity among the nephrotoxicity of light chains. The variable region of the light chain determines nephrotoxicity of the specific light chain by determining the affinity with Tamm-Horsfall protein [98-99]. It has been indicated that Tamm-Horsfall protein interacts with the hypervariable regions of the light chains. This region contains the amino acids that give diversity, and allow for interactions with several proteins to promote antigen binding by immunoglobulins [100-101]. In addition, the variable region of the light chain determines the specific type of renal damage. Both lambda and kappa light chains are nephrotoxic, but lambda light chains are more frequently involved in the formation of amyloid than kappa [102]. The relationship between the type of light chain and the severity and type of renal damage has not been investigated in animals yet.

In addition of casts formation, endocytosis of light chains by renal tubular cells induces pro-inflammatory cytokine production (interleukin-6 and 8, tumor necrosis factor- α). These pro-inflammatory cytokines promote infiltration by inflammatory cells that produce metalloproteinases and increase transforming growth factor- β production, resulting in matrix protein deposition and fibrosis and further compromising the ability of the nephron to restore function [103]. Light chains endocytosis might also cause tubular cell necrosis, leading to more severe renal dysfunction [104], but the exact mechanism has not been described. It has been hypothesized that the aggregation of light chains after endocytosis initiates a cascade leading to tubular cell death [105].

Other mechanisms that lead to renal insufficiency are tumor infiltration within the renal parenchyma, hypercalcemia, amyloidosis, decreased renal perfusion due to the HVS, dehydration, ascending urinary tract infections and Bence-Jones proteinuria [4, 27]. In human patients with MM, hypercalcemia is the second most common cause of renal failure. Hypercalcemia is also probably an important predisposing factor to renal dysfunction in animals with MM, since a tight relationship between renal failure and hypercalcemia has been described in many reports in veterinary medicine [106-108] Hypercalcemia interferes with renal function and impairs renal concentrating ability, causes vasoconstriction of renal vasculature and enhances diuresis.

4.6. Heart disease

Heart disease may occur in patients with MM as a consequence of HVS related to myocardial hypoxia and increased cardiac workload. In addition, amyloid deposition in the myo-

cardium and anemia may exacerbate the severity of this condition [109]. Approximately 50% of the cats with MM in one study had idiopathic heart murmur [4]. Recently, three cases of cats evaluated for congestive heart failure with acute collapse, tachypnea, increased respiratory effort, and pulmonary crackles, have been reported secondarily to HVS [54].

4.7. Other clinical signs

Neurological manifestations often complicate the course of MM, but direct involvement of the central nervous system is rare in human patients, although there are some cases reported [110-113]. Similarly, neurological signs are uncommon manifestations of MM in animals. However, it is well recognized that MM may lead to abnormalities of the central nervous system either as a result of spinal cord compression by the neoplasm arising within a vertebra or due to pathological fracture of a vertebra weakened by tumor infiltration [114-115]. It could also be due to the HVS where sludging of blood within the vasculature results in central nervous system hypoxia [116]. Neurological signs associated with MM have been reported in horses [1,7], cats [31] and dogs [22,114]. Edwards et al. [1] described the cases of three horses with rear leg paresis and/or ataxia. Spinal cord compression by an extradural tumor mass was observed in one of the two horses in which the spinal canal was examined. McConkey et al. [7] observed a horse with hind ataxia progressing to paralysis, with dysphagia and ptialism. These clinical signs were attributed to neoplastic involvement of the trigeminal nerve. Similarly, Appel et al. [31] presented the case of a cat with hind limb locomotor difficulties, signs of pain along the lumbar portion of the vertebral column, with altered motor function and moderate muscle atrophy. In this case, survey radiographs revealed osteolytic lesions in lumbar vertebrae [31].

In MM patients, peripheral neuropathy has for a long time been considered as mainly secondary to the tumor, following a direct compression (radicular or medullar), light chain deposits (amyloidosis), cryoglobulinemia or an autoimmune mechanism [117-121]. A paraneoplastic polyneuropathy is seen in association with IgM monoclonal gammopathy associated with MM, Waldenström's macroglobulinemia, primary amyloidosis and lymphoma, as well as monoclonal gammopathy of undetermined significance. IgM-M proteins have autoantibody activity and have been shown to bind to myelin associated glycoprotein resulting in a demyelinating peripheral neuropathy [121]. However, increased levels of cytokines are thought to cause the paraneoplastic neuropathy rather than an immune-mediated mechanism [122-123]. Furthermore, with the use of new drugs, the iatrogenic neurotoxicity has become the leading cause of peripheral neuropathy in people [124-126]. The commonest nerve involvement appears to be in the form of sensory-motor axonal neuropathy followed by sensory-motor demyelinating neuropathy [117].

In companion animals, paraneoplastic neuropathies have been reported sporadically in malignant tumors, and include bronchogenic carcinoma, insulinoma, leiomyosarcoma, hemangiosarcoma, undifferentiated sarcoma, synovial sarcoma and adrenal adenocarcinoma [114,127-129]. Viviers and Dobson [22] described the case of a 12-year-old female German Shepherd dog that developed progressive hindlimb followed by forelimb ataxia with tetraplegia. Neurological examination suggested lower motor dysfunction. MM was diagnosed

by biochemical evaluation, radiography and bone marrow aspirate. An electromyogram revealed positive sharp waves and fibrillation potentials in the skeletal muscles of the limbs, suggesting a polyneuropathy. Motor function started to improve four weeks after commencing treatment. According to the authors, polyneuropathy in this dog appeared as a paraneoplastic syndrome secondary to MM [22].

Cutaneous involvement in MM has also been described in animals, although it seems to be unusual. Mayer et al. [24] described the case of an 8-year-old Rottweiler dog with more than 50 soft cutaneous and subcutaneous nodules, ranging from 0.5 to 2.5 cm in diameter, located primarily on the ventral aspects of the thorax and abdomen and the medial aspect of the thighs. Histopathological examination of excised subcutaneous modules revealed MM. More recently, Fukumoto et al. [16] presented the case of a 7-year-old male, mixed breed dog with more than 40 cutaneous nodules ranging from 0.5 to 1.0 cm in diameter, mainly on the abdomen and inguinal region. Cutaneous involvement has not been described in horses with MM.

5. Diagnosis aids of multiple myeloma in veterinary medicine

5.1. Hematology

Anemia is a prominent feature of MM, it is commonly associated with clinical progression in human patients and occurs in more than two thirds of all patients [130-132]. Similarly, approximately 30% of dogs and 75% of cats with MM have a normocytic normochromic non-regenerative anemia [4,10,26-27,32-33] and anemia is also invariably present in horses with MM.

The pathogenic mechanisms involved in the anemia are chronic inflammation, tumor hemorrhage and/or hemostatic abnormalities, myelophthysis, increased red blood cell destruction induced by the HVS, plasma expansion secondary to the osmotic effect of the paraproteins and red cell destruction by neoplastic cells [4,27,29]. In cats, erythrophagocytosis by neoplastic plasma cells [32], mast cells [133]), lymphocytes [134-135] and histiocytes [136] has been observed. In the same way, there are several reports of phagocytic plasma cells in people with MM [137]. Although erythrophagocytic plasma cells in humans with MM are rare, neoplastic plasma cells have been observed with phagocytosed platelets and granulocytes [138]. The mechanism of hemophagocytosis in MM is unclear, as plasma cells have not phagocytic function under normal circumstances. Results of the direct antiglobulin test in humans are almost always negative, suggesting hemophagocytosis by neoplastic cells is not an autoimmune function [137]. It has been speculated that phagocytic plasma cells may arise as an expansion of a rare B-cell clone with innate phagocytic potential [137]. A single case of phagocytic plasma cells aberrantly expression CD15 (normally found on neutrophils and monocytes and involved in phagocytosis) has been reported in human beings [139].

Nevertheless, anemia of chronic disease appears to be of utmost importance in MM. Interleukin-1 and tumor necrosis factors are capable of suppressing erythropoiesis [130]. Anemia

has broad implications in these patients. First, the low hemoglobin concentration and packed cell volume have been associated with poor quality of life in people, and affect daily activity. Second, anemia has an impact on the cardiovascular system. In fact, anemia has been shown to induce or aggravate hypoxia and ischemic complications. Third, anemia has been shown to be a poor prognostic factor in MM [140-142].

Data concerning white blood cell count (total and different subpopulations) are not consistent in animals with MM. It has been found lymphopenia [24,30,32], leukocytosis due to neutrophilia [4,8], neutropenia with lymphocytosis [31], leukopenia [1,25,37], leukocytosis with neutrophilia and lymphocytosis [31], neutropenia [16], neutrophenia with lymphopenia [18], pancytopenia [10] and absence of white blood cell abnormalities [3,6,22].

Thrombocytopenia is reported in approximately one third of all canine patients of MM [10,25,27]. It has also been described in cats [4,29] and horses [18,37]. However, there are many other reports of MM in veterinary medicine with patients that show normal number of platelets [3,6-8,16,22,24,31-32]. Thrombocytopenia that could promote bleeding disorders, is proposed to result from infiltration of bone marrow by malignant plasma cells, consumption of platelets as part of thrombohemorrhagic syndrome, such as disseminated intravascular coagulation, shortened platelet half-life or immune-mediated destruction, even though the latter 2 mechanisms have yet to be verified in veterinary medicine [10,27,30,64,142-143].

5.2. Blood clinical biochemistry

5.2.1. Serum protein concentrations and serum protein electrophoresis

Hyperproteinemia, specifically hypoalbuminemia and hyperglobulinemia is very common in MM, but not an invariable feature. Hypoalbuminemia has been described consistently in MM in dogs [9,15-16,22-24], cats [3,9,29,32] and horses [1,3,18]. However, in the three animal species, there are some reports that reported serum albumin concentrations within the reference range in animals [6-8,31].

The mechanisms of the hypoalbuminemia are unknown, but in human beings is primarily related to the extent of the proliferation of the MM and it is therefore of diagnostic and prognostic importance [144]. Several studies have suggested that low serum albumin concentrations correlate with increased serum concentrations of interleukin-6, a potent myeloma cell growth factor, reflecting disease severity and cell proliferation [145-146]. Interleukin-6 is a multifunctional, pro-inflammatory cytokine that stimulates B cell maturation and proliferation and overproduction has been demonstrated in a variety of B-cell malignancies [147].

The neoplastic plasma cells are responsible for an overproduction of a homogeneous or monoclonal immunoglobulin product, known as paraproteins or M-component. The paraproteins may be complete immunoglobulin, free light chains, light chains fragments or polymers, or partial immunoglobulins missing one or both chains [148]. The term monoclonal gammopathy is commonly used to define hyperglobulinemia characterized by an electrophoretic pattern with a sharply defined peak that is usually in the β - or γ - region and is narrower than the albumin peak [9,149]. When 2 narrow peaks with these features are

recognized, the term biclonal gammopathy is often used. Monoclonal gammopathies are associated with production of a single clone of immunoglobulin owing to clonal expansion of neoplastic lymphoid cells, such as plasma cells in MM and B cells in lymphoma [9]. In contrast, a polyclonal gammopathy is characterized by a broader peak or multiple peaks in the γ - or β - γ regions. Polyclonal gammopathies are associated with chronic antigenic stimulation that occurs in chronic infections and other inflammatory conditions [148,150-152]. The term oligoclonal gammopathy refers to an electrophoretic pattern that is similar to a monoclonal one, but in which the globulin peak is slightly wider than the albumin peak [9,149]. Oligoclonal gammopathy may occasionally occur in animals with chronic inflammation or infectious disease [9].

Although monoclonal gammopathy is the laboratory landmark of MM, other conditions occasionally can induce a monoclonal gammopathy in animals, such as chronic inflammation (leishmaniosis, ehrlichiosis, chronic pyoderma, feline infectious peritonitis) [149-150,153-155], amyloidosis [156-157], B-cell lymphoma [149], Waldenström's macroglobulinemia [158-159] and monoclonal gammopathy of undefined significance (MGUS) [160]. The inclusion criterion for MGUS are M-protein and <10% bone marrow plasmacytosis, with no evidence of lytic lesions, light chain proteinuria or other clinical, hematologic, and biochemical abnormalities [161-162]. MGUS occurs in 1-2% of people over the age of 50 and 3% of people over the age of 70 [162]. A significant proportion (25%) of these will evolve within 20 years into MM, primary amyloidosis, macroglobulinemia or another lymphoproliferative disease [162].

In dogs affected by MM, the incidence of IgA and IgG is comparable, whereas in cats and horses IgG is most commonly involved [1,3-4,27]. In fact, of the 25 published feline MM with immunoelectrophoresis results, 20 had IgG gammopathies, and 5 had IgA gammopathies [2,13-14,85]. Similarly, there are some reports of IgA gammopathies in horses with MM [3,8].

Biclonal gammopathy, with two M-components has been reported in humans [163-165], even though it was found to be very rare, occurring in about 1% of human beings with MM [166]. Biclonal gammopathies have been described in lymphoproliferative disorders in dogs and cats [2,9,19,23,167-168] including MM. The term biclonal is applied to the electrophoretic pattern and does not always correlate with true biclonal expansion because the biclonal electrophoretic may arise from a single clone of B-cells, usually mature plasma cells that produce one type of immunoglobulin with different dimerization patterns [9]. The biclonal pattern may also occur from production of two different classes of immunoglobulins, usually IgG and IgA, by two separate cell clones [23]. However, production of separate heavy chain isotypes by a single clone of neoplastic cells, may result from isotype switching, which occurs normally during B-cell maturation [9].

The prevalence of biclonal gammopathy in companion animals is unknown, but it could be higher than reported. In many clinical veterinary laboratories, serum protein electrophoresis is performed using cellulose acetate as the support medium. However, better separation of protein fractions may be obtained using agar cell electrophoresis or capillary zone electrophoresis. Facchini et al. [9] reported two cases (dog and cat) with gammopathies associated

with MM that were interpreted as oligoclonal by standard cellulose acetate electrophoresis but were determined to be biclonal on capillary zone electrophoresis.

MMs in veterinary patients lacking hyperglobulinemia have also been described [10]. The authors propose that the lack of hyperglobulinemia resulted from either M-protein associated secondary hypogammaglobulinemia or the IgA nature of the M protein. Secondary hypogammaglobulinemia with an immunosuppressive phenomenon associated with MM is reported to occur in about 10% of human MM patients, and in a report, is most commonly seen in secretory immunoglobulin A- MM [169-172]. The mechanism underlying MM-associated hypogammaglobulinemia is unclear, but recent work suggest that appropriate B-cell maturation and immunoglobulin production are impaired by defects in CD4+, CD45R+, naïve T cells and increases in CD8+, CD11b+ memory T cells [173-174]. The depression of normal immunoglobulin production associated with exuberant M protein production has been described anecdotally, but not specifically described in dogs with MM [64]. Seelig et al. [10] supported their hypothesis in the immunoglobulin quantification data, which indicate massive production of the immunoglobulin A M-protein and mild to moderate decreases in immunoglobulins G and M in a dog.

Cryoglobulinemia has also been described in human patients with MM [175-176]. Cryoglobulins are proteins, usually immunoglobulins that precipitate as serum is cooled to temperature less than body temperature and dissolve upon rewarming. They are most commonly evident as a white gelatinous material but may sometimes appear crystalline or flocculent [177]. Cryoglobulinemia is rare in animals and are limited descriptions in dogs with MM [114,178], in a dog with Waldenström's macroglobulinemia [179], in a cat [28], in a horse with lymphoma [180], and in several horses with glomerulonephritis [181-182]. In human patients, cryoglobulins are classified into 3 groups on the basis of their immunoglobulin composition. In type-I cryoglobulinemia a single monoclonal immunoglobulin, usually IgM is present. This is most commonly associated with lymphoproliferative disorders such as MM, Waldenström's macroglobulinemia, lymphoma, and lymphocytic leukemia, but occasionally can develop in conjunction with immune-mediated diseases [177]. In type II cryoglobulinemia, a monoclonal immunoglobulin, usually IgM complexes with polyclonal IgG, whereas in type III cryoglobulinemia, polyclonal immunoglobulins, usually immunoglobulin M complex with polyclonal immunoglobulin G. Type II and III cryoglobulinemia and may develop secondary to infection, immune-mediated diseases or very rarely, lymphoproliferative disease. In some instances, an underlying disease is not found and the cryoglobulinemia is described as essential. Using this classification system, type-I and mixed cryoglobulinemia in dogs, horses and cats have been described. Two dogs with MM had type-I immunoglobulin A cryoglobulinemia [114,178] and the dog with Waldenström's macroglobulinemia had type-I immunoglobulin M cryoglobulinemia [179]. Another dog had an essential mixed immunoglobulin G-M cryoglobulinemia and cryofibrinogenemia [183], and although a thorough investigation for the underlying disease was not performed, the diagnosis was supported by resolution and lack of recurrence of clinical signs when the dog was maintained in a warm environment [183]. A cat had type I immunoglobulin G cryoglobulinemia in association with MM [28].

The typical clinical signs of cryoglobulinemia are purpura, cold intolerance, acrocyanosis and ulceration, necrosis and gangrene of the skin of the distal extremities [184]. However of the cases of cryoglobulinemia reported in the veterinary literature, only 1 dog [183] and 2 horses [180,182] had typical lesions. Necrosis of the pinnae occurred in the dog [183] and in 1 of the horses [180] and distal limb swelling and ulceration in other horse [182]. Similarly, <50% of human patients with cryoglobulinemia have typical clinical signs even in cold conditions [184]. The lesions develop as a result of precipitation of cryoglobulin in small-diameter blood vessels, which causes vascular occlusion and tissue ischemia. Subsequently, inflammation may develop at the site of precipitation secondary to complement fixation by immunoglobulin G [185]. Despite extensive investigation, the physical and chemical characteristics accounting for the temperature-dependent solubility of cryoglobulins have not been determined. Proposed mechanisms include altered amino acid or carbohydrate content of the cryoglobulin, leading to abnormal interactions between water and the protein [185].

5.2.2. Serum urea and creatinine concentrations

Azotemia is present in half of MM human patients when first evaluated [78-79]. Similarly, many animals with MM show azotemia when presented [1,4,10,24,27,29], whereas there are other cases with serum urea and creatinine concentrations within the reference limits [3,6,22]. Probably these differences depend on the existence of renal kidney and on the degree of hydration.

5.2.3. Serum total and ionized calcium concentrations

Hypercalcemia has been reported in approximately 15-20% of dogs and 20-25% of cats affected by MM [4,29,65]. Similarly, hypercalcemia seems to be common in horses with MM [1,3,8], although there is a report of hypocalcemia in one horse with MM [18].

Hypercalcemia is a complication of uncontrolled osteolysis, influenced in part by osteoclast activation factor and in human patients has been associated with extensive osteolytic disease [86]. However, MM-associated hypercalcemia is not reported as frequently as bone lysis [4,27,35,64], perhaps because disease progression is usually slow, allowing for appropriate metabolic controls. Other mechanisms of hypercalcemia are the release of an osteoclast activating factor by either the bone marrow microenvironment or by neoplastic cells located in bone [186-190]. In humans, interleukin-1, interleukin-6, tumor necrosis factor and the receptor activator of the nuclear factor kappa B ligand (RANKL) all modulated osteoclast activity and may contribute to hypercalcemia [191]. Parathyroid hormone related peptide (PTH-rP) also may contribute to the pathogenesis of MM-related hypercalcemia. It seems that essentially every cell of the body makes PTHrP under normal conditions [192-193]. It has a broad range of physiological functions, including stimulation of bone resorption, vasorelaxation, and cell proliferation, regulation of placental calcium transport, organogenesis, parturition, lactation, and vascular smooth muscle proliferation and development of the skeletal system [193]. Despite its wide distribution of the body, PTHrP is normally present in minute amounts in the circulation [193-194] and high serum PTHrP concentrations have been found in conjunction only with pathologic conditions, principally malignancy [194-195]. PTHrP

may be synthesized by normal cells activated by the presence of a malignancy or by neoplastic cells. There is a report of a horse with MM and high concentrations of PTHrP [8]). High levels of PTHrP have been also described in other neoplasms, such as thymoma [196], nasal carcinoma [197], squamous cell carcinomas [198], angiomyxoma [199], mammary carcinoma [200], lymphoma [201-203] adenocarcinoma of the apocrine gland of the anal sac [203] and malignant melanoma [204].

The measurement of ionized calcium is recommended to confirm hypercalcemia in these patients, because binding of calcium by the M protein will increase total calcium concentration, while ionized calcium will remain within normal limits [205]. Therefore, increased ionized calcium concentrations supports true hypercalcemia. There is a recent report that present a case of MM in a dog with increased total serum calcium concentration, but with serum ionized calcium concentrations within normal limits [25]. The authors suggested that the majority of the calcium was protein-bound to serum M proteins. In fact, serum calcium exists in two major fractions, free and protein bound. A small portion of calcium is bound to other small anions such as citrate, lactate, and phosphate. Because ionized calcium is the physiologically active species of blood calcium, it is ordinarily maintained within very narrow limits by rigidly controlled mechanisms [205-206]. Approximately half of normal total serum calcium is bound to negatively charged sites on albumin. Human MM has been reported to bind calcium on the Fab portion of the globulin molecules [148].

MM is frequently complicated by an increase in the concentration of ionized calcium, which if persistent leads to secondary nephrogenic diabetes insipidus and loss of the renal medullary concentration gradient causing polyuria and polydipsia [25].

5.2.4. Alterations in the coagulation profile

Approximately 50% of dogs affected by MM have abnormal prothrombin and partial thromboplastin times [149,207] and these abnormalities have also been found in horses [6,18,37,86] and cats [4,29]. However, other animals with MM had normal bleeding times [3,22].

Coagulation defects can result from paraproteins interference with clotting factors, protein coating of platelets leading to thrombocytopenia and binding of the Fab fragment of the M-protein to fibrin, preventing aggregation [116,208].

5.2.5. Alterations in serum sodium concentrations

Three horses with MM were hyponatremia [1]. The decreased concentrations could have resulted from displacement of the aqueous phase of plasma by the hyperglobulinemia. However, true hyponatremia in human beings with MM has been described. Suggested mechanism include displacement of sodium by cationic paraproteins, decreased plasma water secondary to unusual hydration characteristics of paraproteins, and syndrome of inappropriate antidiuretic hormone release [209-210]. Alterations in serum sodium concentrations do not appear to be common in small animals.

5.2.6. Alterations in serum cholesterol concentrations

Hypocholesterolemia has been noted in approximately 69% of affected cats in one study [4]. Similarly, hypocholesterolemia was found in a horse with MM [1]. The incidence in cats is higher than in human patients [211-212]. Serum cholesterol concentrations are thought to be correlated inversely with globulin concentrations [35,211]. It has been postulated that the hypocholesterolemia is the result of a down-regulation of cholesterol production by the liver to maintain oncotic pressure in the face of hyperglobulinemia [78]). The main causes of hypocholesterolemia in veterinary medicine include protein-losing enteropathies, severe malnutrition, hepatic insufficiency or hyperthyroidism [213-215].

5.3. Urinalysis

Proteinuria, detected by routine urinalysis is present in 90% of human patients with MM [216-221]. In the same way, proteinuria using dipsticks has been found in horses [1,3,6], dogs [10,22] and cats [4,28,30,32] with MM. However, dipsticks detect primarily albuminuria and therefore, the sulfosalicylic acid test (SSA) provides greater sensitivity for globulin detection but specificity is low due to the concomitant detection of albumin, globulin, Bence Jones proteins, proteases and polypeptides. False positive SSA results may occur with penicillin and its derivatives, tolbutamide or sulfisoxazole metabolites, or certain contrast media in the urine [222]. In people, false positive results for Bence Jones proteins detected by means of heat precipitation can occur due to excessive amount of polyclonal light chain proteins in patients affected by a variety of conditions, including connective tissue diseases, non-plasmacytic tumors and chronic renal failure [4,216,222]. Therefore, urine protein electrophoresis remains the preferred diagnostic modality to detect monoclonal proteinuria, even is not always used in veterinary medicine.

Bence Jones proteinuria has been estimated to occur in approximately 25-40% of dogs and approximately 65% of cats with MM [4,27,29]. Similarly, it has been determined in horses with MM [1,3].

5.4. Diagnostic ancillary aids

Survey radiographies and echographies are required for screening of skeletal lesions and identification of abdominal organ neoplasia respectively. Furthermore, a fundoscopic examination should be carried out in patients suspicious of MM, mainly in small animals, in order to rule out ocular lesions associated with the HVS, such as retinal hemorrhages, retinal detachment, venous tortuosity, dilation, sacculation, and blindness.

As explained before, skeletal lesions vary from areas of osteopenias observed in early stages of the disease to lytic lesions typical of later stages. Biopsy and histopathology of a lytic lesion may sometimes be necessary for a definitive diagnosis. Survey radiographies are commonly performed now in small animals with MM, because increased clinician awareness of the lesions, better quality radiographs and increased knowledge about the disease. In horses with MM, survey radiographies are less used, probably because of the higher incidence of skeletal lesions of other origin (sport horses). Lung radiography is recommended in equine

patients with MM in order to rule out pneumonia, one common finding in these cases [3,18]. In addition, hepatomegaly (58%), splenomegaly (25%), cardiomegaly (67%) and renomegaly (9%) have been detected in cats with MM [4,29].

The most common ultrasonographic abnormalities involved the spleen and the liver and to a lesser extent the kidneys [4]. In cats, the most consistent finding in MM is splenic enlargement and diffuse or nodular hypoechogenicity. The most consistent hepatic abnormality is diffuse hyperechogenicity and enlargement [4]. Bone marrow cytology should be done to confirm the diagnosis. A detailed description of the histopathological characteristics in bone marrow and in other organs after necropsy, consistent with MM is out of the scope of the present review.

5.5. Diagnostic criteria

Current published recommendations for determining a diagnosis in veterinary medicine indicate that the animal should have at least 2 of the following 4 criteria: 1) Bone marrow plasmacytosis with >20% plasma cells; 2) Monoclonal gammopathy based on serum protein electrophoresis; 3) Osteolysis and 4) Light chain (Bence-Jones) proteinuria (2). These criteria are unweighted for animal patients. In human patients, criteria are weighted as 'major' and 'minor' and accommodate lower plasma cell percentages (17). In people, confirmation of MM requires first that the patient be symptomatic (i.e. have bone pain) or have anemia, hypercalcemia, azotemia, hypoalbuminemia, or bone demineralization. The diagnostic criteria of MM are then applied. Major criteria include: 1) plasmacytoma(s) with biopsy; 2) marrow plasmacytosis >30%; 3) M-protein with >3.5 g/dl immunoglobulin G or 2.0 g/dl immunoglobulin A and 4) κ or λ chain excretion on 24-h urine protein electrophoresis. The 4 minor criteria include: a) marrow plasmacytosis with 10-30% plasma cells; b) M-protein at values less than indicated above; c) lytic bone lesions and d) >50% normal serum immunoglobulin concentration. If the diagnosis includes major criteria, then any 2 of the 4 will suffice, or major criterion 1 plus minor criterion b, c, or d; or major criterion 3 plus minor criterion a or c. If the diagnosis is based on only minor criteria, then it must include the first and second criteria (a and b), plus 1 of the remaining 2 criteria (c or d). This system has been recently incorporated for the diagnosis in animals [4,10,24,31-32]. However, some modifications have been introduced. Plasma cell atypia has been included as a criterion when marrow plasmacytosis was between 10 and 20%. In humans, nuclear-cytoplasmic maturation asynchrony, nuclear immaturity, and pleomorphism are considered reliable markers for distinguishing neoplastic cells from reactive plasma cells [223]. In addition, reactive plasma cells usually do not exceed 5% of all nucleated cells in marrow and are well differentiated [223-224].

6. Treatment options in veterinary patients with mm

Treatment of MM with oral melphalan and glucocorticoids (prednisone or prednisolone) is the standard of therapy due to its dual ability to reduce the bulk of the tumor and the symptoms of the disease [16,22-25,31-33,225]. Although complete eradication is only rarely ach-

ieved, chemotherapy is often effective in decreasing tumor burden, reducing serum immunoglobulin levels, promoting bone remodeling and providing symptomatic relief. Further, this treatment leads to improved quality and possible duration of life [27,225] and is also used in human patients with MM [226-230].

Melphalan is an alkylating agent whose oral absorption is unpredictable, requiring administration to be made preferable on the empty stomach. In dogs, melphalan is initially administered at 0.1 mg/kg PO once a day for 10 days and then 0.05 mg/kg PO every other day. In cats, they are administered at 0.5-2.0 mg/kg PO once a day. Melphalan is combined with glucocorticoids, prednisone [22,24-25,42] or less common, prednisolone [25,30-31]. Glucocorticoids have been shown to induce apoptosis *in vitro* via inhibition of I κ B activation and decreased nuclear factor κ B activity [231-232]. Prednisone in dogs with MM is generally administered at 1.0 mg/kg for the first 10 days of therapy and then, decreased to 0.5 mg/kg every other day [22,24-25,32,225]. This combination treatment is continued indefinitely, until relapse or myelosuppression.

Other alkylating drugs including cyclophosphamide, chlorambucil and 1(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU) have also been used to treat MM in small animals [10,233]. The addition of cyclophosphamide to a prednisone- melphalan regimen may be beneficial to patients with severe clinical signs and/or hypercalcemia. Due to its platelet-sparing effect, cyclophosphamide may be used in place of melphalan in thrombocytopenic patients, although this drug can have severe suppressive effects on other bone marrow lineages [234-237]. Chlorambucil, administered at 0.2 mg/kg PO once daily has been used successfully for the treatment of immunoglobulin M macroglobulinemia in dogs [159].

Combination chemotherapy protocols incorporating vincristine, carmustine, melphalan, cyclophosphamide and prednisone or vincristine, melphalan, cyclophosphamide and prednisone have been used in human beings, but outcomes are essentially comparable to those of patients with melphalan and prednisone alone [238-241]. The administration of high dose dexamethasone in conjunction with vincristine and doxorubicin was investigated in humans with refractory MM and resulted in a response greater than 50%. Rapid tumor response, alleviation of bone pain, resolution of hypercalcemia and absence of damage to bone marrow stem cells were remarkable advantages to this treatment combination [239]. Anecdotally, in dogs, responses of a few months duration have been achieved with a combination of doxorubicin, vincristine and prednisone in lymphoma [242-243] and in MM [10].

The efficacy of interferon for the treatment of MM is controversial [244-245]. While a response rate of approximately 20% was reported in humans with relapsed MM, the addition of interferon to standard chemotherapy approaches failed to provide a significant benefit to the overall survival time in a meta-analysis of 2286 patients [244]. However, there is other report that stated that even though most interferon benefits to MM patients are relatively small when viewed in the light of survival expectancies, they seem clinically relevant. Since median overall survival of conventionally treated MM patients ranges between 30 and 50 months, 3-7 months gains of life amount to an increase of 10-25% [244].

High-dose chemotherapy in association with autologous transplantations using bone marrow or blood-derived stem cells is now widely accepted for the treatment of hematological malignancies including MM. This approach yielded to complete remissions in refractory human patients, but mortality rate due to bone marrow suppression was high. Contamination of most bone marrow and blood stem cell samples with neoplastic cells within the autograph resulted in recurrence of disease, emphasizing the need of optimize purging techniques [246-250]. Autologous bone marrow transplant has also been added to chemotherapy in the treatment of some malignancies in companion animals, such as lymphoma and acute myeloid leukemia [251-253].

In human patients with MM, biphosphonates such as pamidronate, have been used to prevent or to delay the onset of bone lesions and associated bone pain [254-257]. Bisphosphonates have been administered in dogs with appendicular osteosarcoma [258-259] and with malignant histiocytosis [260], but they have not been used in veterinary patients with MM.

Treatment of patients affected by indolent MM with the anti-angiogenic agent thalidomide resulted in a 66% response rate and the drug appeared to have potential to delay the onset of clinical signs associated with the disease [261-262]. The efficacy of thalidomide for the treatment of refractory relapsed MM has also been confirmed [263-265]. Studies evaluating the possible efficacy of thalidomide for the treatment of MM in companion animals are lacking. Bortezomib, a proteasome inhibitor, induces apoptosis of MM cells and inhibits their binding to bone marrow stromal cells, which otherwise would trigger the transcription of interleukin-6 via an NF κ B-dependent pathway. In different studies a 25% response rate was achieved in human beings with MM and an overall survival time of 16 months. Furthermore, addition of dexamethasone to the treatment regimen improved responses in 19% of treated patients [227-228,264,266].

Additional, some patients experience severe clinical signs secondary to hypercalcemia, renal dysfunction, HVS or pathologic fractures will require palliative therapy specifically directed to the clinical complications of the disease.

7. Prognosis of companion animals with multiple myeloma

Unfortunately, the prognosis of companion animals with MM is poor. The mean survival time in dogs treated with MM and treated with melphalan, cyclophosphamide and prednisone is 540 days after diagnosis [27]. In dogs, negative prognostic factors include extensive bone lesions, hypercalcemia and light chain proteinuria. Renal insufficiency and poor initial response to therapy also may be associated with decreased survival times [27]. In a study of 9 cats with MM, it was found that hypercalcemia, pathologic fractures, anemia, Bence-Jones proteinuria, azotemia, persistent elevations in serum protein concentrations at 8 weeks after treatment and little or no clinical improvement were poor prognostic indicators and reflected a more aggressive form of the disease [29]. Survival time for such cats did not exceed 14 days, with a median of 5 days. In contrast, normocalcemia, lack of azotemia, absence of pathologic fractures, no anemia, absence of Bence-Jones proteinuria and a normal serum

protein 8 weeks after commencement of treatment reflected a less aggressive form with a median survival of 387 days (range between 120 and 720 days) [29].

In a study, a possible relationship between prognosis and immunoglobulin isotype was suggested in cats with MM [2], even though there are few detailed cases. Although immunoglobulin A appears to be less commonly produced than immunoglobulin G in cats, as described before, the published cases with immunoglobulin A paraproteins had visceral involvement and decreased survival time (ranging from a few days to 6 months) [12,65,267-268]. Either immunoglobulin has been associated with clinical signs of HVS, including cardiac insufficiency, retinal hemorrhages and neurological signs [85,268]. This phenomenon relates to the size of the paraproteins and the degree of hyperglobulinemia. Since immunoglobulin A may assume a dimeric or multimeric form, it may be more commonly associated with hyperviscosity than immunoglobulin G. HVS can contribute to decreased survival time in animals with MM [13,23,54,85].

The lifespan of horses diagnosed of MM usually does not exceed two years [1,3,6,8]. There is not any published case of equine MM that attempted chemotherapy and most horses are euthanized owing to the advance stage of the disease.
