1. Introduction

Ceramic nanocomposites are often defined as a ceramic matrix reinforced with submicron/nano sized particles of a secondary phase. The advantages of these nanocomposites include: improved mechanical properties, surface properties, high thermal stability and superior thermal conductivity. It is very fascinating/interesting for the researchers to synthesize these composites as the incorporation of few percent nanosized particles changes the materials property substantially. Niihara et al.,[35], [36] have reported that the mechanical properties of ceramics can be improved significantly by dispersing nanometer-sized ceramic particles into ceramic matrix grains or grain boundaries. According to their observation, 5 vol% of silicon carbide nanoparticles into alumina matrix increases the room temperature strength from 350 MPa to approximately 1 GPa. Other strength improvements through similar approaches have been observed in alumina-silicon nitride, magnesia-silicon carbide, and silicon nitride-silicon carbide composite systems.

Apart from the basic mechanical properties such as such as micro hardness, facture strength, and facture toughness [9; 23; 44], nanocomposites also exhibit electro conductive, wear resistance, creep resistance and high temperature performance [10; 24; 37; 38, 39] However, the degree of improvement in these properties is dependent on the type of composite system involved.

1.1. Novel Synthesis of Ceramic nanocomposite

Chemical Vapor Deposition (CVD) is a very preferable method to disperse the nano-sized second phases into the matrix grains or at the grain boundaries [33]. However, the CVD process is not applicable to fabricate the large and complex shaped component for the mass produc-
tion and also it is very expensive. Processing route is another technique to prepare ceramic nanocomposites. Following the initial work of [34], several research groups have tried to synthesize the nanocomposites using different processing route such as conventional powder processing [6; 8], hot press sintering [25; 47] sol-gel processing [30; 50] and polymer processing [5; 16]. The ceramic nanocomposites can be synthesized using microwave plasma [48; 49]. The main advantage of this technique is that the reaction product does not form hard agglomerates because of the specific conditions during synthesis.

![Figure 1. Schematics of Spark Plasma Synthesis (SPS) process](image-url)

Recently developed Spark plasma sintering (SPS) is a novel sintering technique that uses the idea of pressure driven powder consolidation under pulsed direct electric current passing through a sample compressed in a graphite matrix. It is also known as the field assisted sintering technique or pulse electric current sintering. This newly developed sintering technique is regarded as an energy-saving technology due to the short process time and fewer processing steps. This technique was first described by Raichenko, 1987 and the key characteristics of this SPS are given as follows:

i. The generation of local electric discharge plasma and its effect on the material.

ii. The combined effect of external fields, such as a force field and electric field, on the densification and phase formation in a particulate system.

iii. The influence of electric current in the near surface layers of conductors and semiconductors (the so-called “skin-effect”).

iv. The rapid and nonuniform heating/cooling throughout the sample, causing large temperature gradients.
The schematic of SPS process is shown in Fig.1 [41].

1.2. Advantages of SPS over other synthesis method

The most impressive advantage of SPS is its applicability to sinter materials of various types of chemical bonding and electric conductivity. Novel materials have been prepared from powders of ceramic dielectrics, conductors, semiconductors, amorphous alloys, and, sometimes, polymers. The traditional driving force involved in commonly used consolidation techniques such as solid state sintering and hot press sintering are: surface tension, external pressure, chemical potential due to the gradient of surface curvature, concentration gradient in multicomponent system etc. In SPS technique, the additional driving forces include electromechanical stress, high local temperature gradients creating thermal stresses intensifying thermal diffusion, and dislocation creep. These additional driving forces are responsible for much faster transport mechanism, that accelerates rapid sintering, which is observed in SPS.

1.3. TiN/Si₃N₄ Ceramic Nanocomposites

Si₃N₄ ceramics are regarded as one of the important high temperature structural materials. These ceramics have attracted much attention due to their good mechanical and chemical properties and due to their reliability at room and elevated temperatures [14; 19]. High strength and high-toughness Si₃N₄ matrix composites such as whisker-reinforced of particulate-reinforced ceramics, have been developed to improve the mechanical reliability of Si₃N₄ ceramics [2; 13]. However, these composites are extremely hard and machining using conventional tools is difficult, which limits the widespread application of these materials in many fields. If, sintered Si₃N₄ bodies can be made electro conductive, electrical discharge machining (EDM) technique can be applied to manufacture complex components [32]. It has been reported that introduction of electro conductive second phase can improve the mechanical properties and electroconductivity of Si₃N₄ ceramics [14; 18; 43].

TiN exhibits a number of desirable properties, including high hardness, good chemical durability, high electrical conductivity and is a popular second phase additive due to its good compatibility with Si₃N₄. It often incorporated into the β-Si₃N₄ matrix as cutting-tool materials [4; 14; 17; 28]. There are two advantages to the Si₃N₄ based composites. First of all, the good physical properties of TiN, such as high melting point, hardness, strength and chemical stability, as well as its good erosion and corrosion resistance, enable it to be an excellent toughening material [7; 28; 51]. Secondly, the electrical resistance of Si₃N₄ can be substantially decreased, which consequently makes electric-discharge machining possible [17; 21].

2. Spark Plasma Sintering of TiN/Si₃N₄ nanocomposite

As described in the previous section, SPS is a newly developed sintering technique and it is beneficial to consolidate Si₃N₄ based nanocomposites in a short time. Some researchers have already reported that TiN/Si₃N₄ based nanocomposites with excellent mechanical properties and conductivity can be processed through a chemical route and sintered by SPS [1; 22].
However, due to the complexity of these processing techniques, they are not suitable for large scale production. The planetary milling process has been introduced in their study. Moreover, the details of microstructural development of $\text{Si}_3\text{N}_4$ and TiN have not described, especially in the presence of a pulse direct current through the sintering compact during a sintering cycle.

In the present study, we have prepared TiN/$\text{Si}_3\text{N}_4$ nanocomposite using SPS from $\text{Si}_3\text{N}_4$ and TiN nano powders. The $\text{Si}_3\text{N}_4$ and TiN nano powders were applied because they are sensitive to the microstructural changes during the sintering process. The relationship between microstructure and performance, like mechanical properties and electrical conductivity, of these TiN/$\text{Si}_3\text{N}_4$ nanocomposites are discussed. Finally, the effect of nano-TiN on the mechanical behavior of $\text{Si}_3\text{N}_4$ based nanocomposite has been investigated in sufficient details.

### 2.1 Experimental Details

#### 2.1.1. Preparation of TiN/$\text{Si}_3\text{N}_4$ nanocomposite powder

Commercially available $\text{Si}_3\text{N}_4$ nano powder (SM131, Fraunhofer-Institut fur Keramische Technologien and Sinterwerkstoffe, Dresden, Germany) doped with sintering additives of 6 wt% $\text{Y}_2\text{O}_3$ and 8 wt% $\text{Al}_2\text{O}_3$ was taken as raw material for the matrix phase. It contains 90 wt% $\beta$-phase and 10 wt% $\alpha$-phase, with a manufacturer-determined average particle size of 70nm by the Rietveld method. Nanosized TiN with size of $\sim$30nm (Hefei Kiln Nanometer Technology Development, Hefei, China) was used as secondary phase and it was mixed with $\text{Si}_3\text{N}_4$ nano powders. The composition was chosen to yield a TiN content of 5, 10, 15, 20, and 30 wt% in the final product. The specimen designations and corresponding TiN/$\text{Si}_3\text{N}_4$ ratios in volume percentage (vol.%) for each composite are shown in Table 1. The mixing powders were ultrasonically dispersed in ethanol for 15 min, and then mixed by planetary milling at a rotation speed of 300rpm for 6 h using a 375 ml nylon bottle with $\text{Si}_3\text{N}_4$ balls. The powder mixture was dried in a rotary evaporator, iso-statically cold-pressed into round ingots at a pressure of 200 MPa, crushed and then passed through a #200 sieve for granulation.

2.1.2. Preparation of sintered bodies by SPS

The granulated powders were loaded into a graphite mold with a length of 50 mm and inner and outer diameters of 20 and 50 mm, respectively. A graphite sheet was inserted into the small gap between the punches and mold to improve the temperature uniformity effectively. The graphite mold was also covered with carbon heat insulation to avoid heat dissipation from the external surface of the die. After the chamber was evacuated to a pressure of 10 Pa, the sample was heated to 1600°C under a uniaxial pressure of 30 MPa by SPS (Dr. Sinter 1050, Sumitomo Coal Mining, Kawasaki, Japan). All the SPS measurements were carried out with a heating rate of 200°C/min and holding time of 3 min. A 12 ms-on and 2 ms-off pulse sequence was used. The heating process was controlled using a monochromatic optical pyrometer that was focused on the surface of the graphite mold.

2.1.3. Characterization of sintered bodies

The effective densities of the sintered composites were measured by the Archimedes principle. Phase identification was performed by an X-ray diffractometer (XRD; Model D-MAX/IIB, Rigaku, Tokyo, Japan). Cell dimensions were determined from XRD peak data using UNITCELL with a Si standard. A semiconductor parameter analyzer (HEWLETT PACKARD 4140B, USA) was used to determine the electrical resistivity of the samples. The upper surfaces of the sintered samples were polished down to 1μm. Hardness was measured with a Vickers hardness tester (AKASHI AVK-A, Japan) and by applying a micro-hardness indent at 196N for 15 s. Fracture toughness was measured by the Vickers surface indentation technique [12]. The polished and plasma etched surfaces were used for microstructural characterization by field emission scanning electron microscope (FESEM, XL-40FEG, Philips, The Netherlands). A thin specimen was prepared with a focused ion beam system (FIB, SEIKO, SMI3050, Japan). Transmission electron microscopy (FEGTEM, Tecnai G2 F20, Philips, Eindhoven, Netherlands) was used to characterize the TiN grain of the sintered sample.

2.2. Results and Discussion

2.2.1. Phase Identification of nanocomposite powders by XRD

Fig.2 shows the typical X-ray diffraction patterns of sintered TiN/Si₃N₄ composites with varying TiN content. These composites consist of the β-Si₃N₄ phase as a major phase along with coexistence with secondary TiN phase. The intensity of TiN peaks continues to increase with increasing TiN content. The value of the lattice constant for TiN is 4.25Å, approaching that of pure TiN. On the other hand, the values for a₀ and c₀ for the β-Si₃N₄ phase are 7.61 and 2.91Å, respectively, which are somewhat deviated from those for pure β-Si₃N₄ (+0.01Å). This result suggests that a tiny amount of Si–N may be replaced by Al–O in the particle dissolution and coarsening stages of liquid phase sintering and form the β-SiAlON phase [45].
2.2.2. Densification Behavior

The apparent density of samples containing up to 30 wt% TiN is presented in Fig. 3. The apparent density is found to increase with the increase of TiN content. The increase in density is as predicted, because the theoretical density of TiN (5.39 g/cm$^3$) is substantially greater than that of monolithic Si$_3$N$_4$ (3.19 g/cm$^3$) (Lide, 2002). No obvious pores are also observed on the polished surfaces of the samples (Fig. 4), which suggest the TiN/Si$_3$N$_4$ composites are near full densification.
2.2.3. Microstructure Observation of Nanocomposites

The backscattered electron images in SEM of the polished surface of composites with varying TiN content are shown in Fig. 4. As stated earlier, the samples were sintered at 1600°C for 3 min with a heating rate of 200°C/min in a vacuum. The lighter and heavier atoms in the backscattered images show up as the gray and white regions corresponding to the β-SiAlON matrix (including glassy phase) and TiN particles. Therefore, the TiN particles are distributed homogeneously in the β-SiAlON matrix. However, most of the TiN appear as submicrosized grains, which are much larger than the size of the starting nano powders.

The typical bright field and dark field images of the TiN grain for the as-sintered composite containing 10 wt% TiN content are shown in Fig. 5(a) and (b), respectively. Fig. 5(c) presents the [0 1 1] selected area diffraction pattern (SAD) for the submicrosized TiN grain, and it shows the existence of a twin structure. The results suggest that grain growth and coalescence of TiN occurs in the composite during the spark plasma sintering process in a short time.
The typical micrographs of β-SiAlON grains with different TiN content are presented in Fig. 6. In general, the TiN in TiN/Si₃N₄ based composite inhibits grain boundary diffusion and reduces the grain size of the Si₃N₄ matrix [20]. However, for the special case of 10TN among all these composites, the large, elongated grains can be obtained. The conductive phase of TiN might play an important role in the microstructural development of TiN/Si₃N₄ based composites. The electrical resistivity of TiN (3.34×10⁻⁷Ω.m) [14] is in the range of metallic materials. Although a tiny current appears as measured by a semiconductor parameter analyzer, it is reasonable that a large current might be induced in the presence of pulsed electrical field during sintering. A leakage current might go through the sintering compact during a heating process, and a similar phenomena is also proposed in ferroelectric ceramics [30; 45], and TiCxOyNz/Si₃N₄ based nanocomposites [31]. Therefore, it is expected that a direct current might hop across conductive TiN grains embedded in the insulating β-SiAlON matrix when applying a pulsecurrent. A temporary high temperature might occur in the specimen, and consequently accelerate the grain coarsening behavior of β-SiAlON during a sintering cycle.

Except for the case of the 10TN composite, most of the β-SiAlON grains for the composites have an equiaxial shape with a grain size of less than 200nm (as shown in Fig. 6), whereas a tiny amount of elongated grains with a grain width of 100nm were observed. For the composite of 5 TN, the percolation concentration is too low (i.e. the interparticle distance of TiN is large) to allow a pulse current to pass through the sintering body [52]. For the samples of 15 TN, 20 TN, and 30 TN, the TiN phase significantly inhibits the grain growth of the β-SiA-
ION matrix, even though it is possible for a pulse current to pass through the samples during sintering.

Figure 6. SEM micrographs showing the etching surface of TiN/Si$_3$N$_4$ composites with varying TiN content.

2.2.4. Electrical Properties

The change in electrical resistance for the above composites with varying TiN content is shown in Fig. 7. The electrical resistance substantially decreases from $2.43 \times 10^{10}$ (5 TN) to $1.93 \times 10^8$ (20 TN) ($\Omega$·m) with the increase in TiN content, whereas it suddenly increases to a value of $4.19 \times 10^{10}$ ($\Omega$·m) for composite 30 TN. It has been reported that if the fraction of conductive TiN phase in the composite is under the degree of percolation threshold, the insulating property of the composites is maintained as the electrical resistance of non-conductive Si$_3$N$_4$ matrix [52]. This suggests the TiN phase does not form a connective network. As it is evidenced from Fig. 4, the submicronized TiN grains are nearly isolated from each other. Moreover, the change of electrical resistance possibly depends on the grain size of the conductive phase [11]. Compared with the special cases for 20TN and 30 TN, the larger particle size of TiN for 30TN increases the interparticle distance, leading to a higher magnitude of electrical resistance over composite 20 TN.
2.2.5. Mechanical Properties

The mechanical performance of the above nanocomposites has been studied from hardness and toughness measurements. Indentation hardness is a measure of resistance of a sample to permanent plastic deformation due to a constant compression load from a sharp object. This test works on the basic premise of measuring the critical dimensions of an indentation left by a specifically dimensioned and loaded indenter. Vickers hardness is a common indentation hardness scale, which was developed by Smith & Sandland [42]. Vickers test is often easier to use than other hardness tests since the required calculations are independent of the size of the indenter, and the indenter can be used for all materials irrespective of hardness. The influence of the TiN content of TiN/Si₃N₄ based nanocomposites on the Vickers hardness is shown in Fig. 8. The hardness value for these composites decreases with an increasing amount of TiN phase in the β-SiAlON matrix, and a similar trend was also observed by Lee et al., [31].

Figure 7. Change of electrical resistance of TiN/Si₃N₄ composites with varying TiN Content.

Figure 8. Vickers hardness of TiN/Si₃N₄ composites with various TiN content.
Fracture toughness describes the ability of a material containing a crack to resist fracture, and is one of the most important properties of any material for virtually all design applications. It is also a quantitative way of expressing a material's resistance to brittle fracture when a crack is present. The fracture toughness of the composites containing various compositions of TiN measured by the indentation technique for composites is shown in Fig. 9. The monolithic Si$_3$N$_4$ ceramics have the highest value of 5.4 MPa.m$^{1/2}$. Among the TiN/Si$_3$N$_4$ composites, the toughness reaches a maximum value of 4.9 MPa.m$^{1/2}$ for the composite containing 10 wt% TiN, whereas the other composites have values lower than 4.2 MPa.m$^{1/2}$. An equation derived by Buljan et al., 1988, which expresses the increase in toughness as function of grain size under the assumption that the grain shapes are the same, is given by

$$dK_c = CK_c^0 \left( \frac{D}{D_0} - 1 \right)$$

Where $C$ is a coefficient dependent on the mode of fracture; $K_c^0$ and $D_0$ are the initial toughness and grain size; $dK_c$ and $dD$ are the respective changes in toughness and diameter. Hence, the changes in grain size and shape are directly related to toughness. An increase in Si$_3$N$_4$ grain size results in increasing fracture toughness. Although the addition of TiN does not improve the mechanical properties of Si$_3$N$_4$ based composites, the special sintering behavior produced by pulse direct current (grain coarsening effect for Si$_3$N$_4$ based grain) may occur in a SPS process.

3. Conclusions

i. By utilizing Si$_3$N$_4$ and TiN nano powders as starting materials, a series of near-fully dense TiN/Si$_3$N$_4$ based nanocomposites containing varying TiN contents (5–30 wt %) have been fabricated successfully by a spark plasma sintering technique.
ii. A grain coalescence of the TiN phase has been demonstrated by TEM. The conductive TiN grains in the insulating Si₃N₄ matrix are observed to be isolated from each other. From the microstructural observations, the composites appear to be insulating materials.

iii. For the nanocomposite of 5 TN, 15 TN, 20 TN, and 30 TN, the TiN phase inhibits the grain growth of Si₃N₄ based grains during sintering. Hence, the nanosized Si₃N₄ based crystallites are maintained in size as the raw material.

iv. The spark plasma sintered TiN/Si₃N₄ based composite containing 10 wt% TiN achieves the largest grain size and the highest toughness of 4.9 MPa. m¹/² compared to the other composites. A possible pulse current sintering mechanism might occur, which causes a temporary high temperature in the sintering compact, and then accelerates the grain coarsening of Si₃N₄ based grains.
