Genetic Causes of Syndromic and Non-Syndromic Congenital Heart Disease

Akl C. Fahed and Georges M. Nemer

Additional information is available at the end of the chapter

http://dx.doi.org/10.5772/48477

1. Introduction

Congenital heart disease (CHD) is the most common human congenital defect, and a leading cause of death in infants. With an incidence that varies between 0.8 to 2% in neonates, congenital heart disease contributes to a much larger fraction of stillbirths. (Goldmuntz 2001; Loffredo 2000) Additionally, undiagnosed mild malformations of the heart often appear later in adulthood or remain undiagnosed for life. If these are included, some expect a prevalence of CHD that is up to 4% among all newborns. (Loffredo 2000) An additional contributor to the rising prevalence of CHD among adults is the advance in diagnostics and medical and surgical treatments of children with CHD, which is allowing them, in the majority of cases, to get their heart defect, fixed and sustain a normal life into adulthood. (van der Bom and others 2011) Management of the increasing number of adult patients living with CHD is becoming more and more complicated due to the fact that many patients with mild cardiac lesions are missed during childhood and later appear with complications due to these defects such as heart failure, but even more due to the improvements in diagnosis and surgical care of pediatric patients which are allowing them to survive to adulthood and have their own children.

The majority of CHD is thought to result from gene mutations. This was suggested by early observations of Mendelian inheritance of CHD in families. Another evidence came from congenital syndromes due to micro and macro deletions of chromosomal regions that would result in CHD together with several other manifestations. Over the past few decades, and with the advent of gene sequencing and other techniques it became possible to identify the genetic causes of CHD. (Goldmuntz 2001) In syndromic cases, although it was possible to identify the chromosomal deletions causing the disease, in many cases the gene responsible for the heart phenotype remains undefined. Other syndromes were found to be due to single gene defects; however, for the majority, the downstream pathophysiology linking the
gene defect to the development of disease remains obscure. In parallel, extensive in-vitro and in-vivo studies widened our understanding of the molecular basis of heart development. It is thought that perturbations during embryonic heart development are at the origin of CHD. These studies resulted in large sets of candidate genes and molecular pathways involved in heart development. It is hypothesized that mutations in these genes cause CHD. This was confirmed by sequencing of genes encoding cardiac-enriched transcription factors such as \textit{GATA4}, \textit{NKX2-5}, and \textit{TBX5} in non-syndromic cases of CHD, and finding mutations that segregate with the disease. This prompted excitement in the field; however, screening of large cohorts of isolated CHD cases brought some disappointment as these genes explained only a minority of the cases.

The understanding of how defects in these genes cause CHD turned out to be more complicated than initially expected. It became evident that not all CHD manifests true Mendelian inheritance. It is possible that combinations of mutations in different genes result in a particular phenotype, or combination of a gene mutation with a particular environmental exposure results in a CHD phenotype. Mutations might have low penetrance and only serve to increase the risk of CHD. Other mutations might yield totally defective proteins, yet be compensated for by other proteins in interlinked pathways. Copy Number Variations (CNVs), altered transcription, somatic mutations, and microRNA (miRNA) are also additional mechanisms through which the molecular basis of CHD can be explained. Current research explores all of these mechanisms with a wide array of technologies that are better than ever, and hence the future decade promises a near complete understanding of heart development and the genetic basis of Congenital Heart Disease.

This chapter covers the genetics of syndromic and non-syndromic congenital heart disease. It discusses all genes that have been associated with congenital heart disease in humans with depiction of the spectrum of mutations and the genotype-phenotype correlations for each. The chapter also covers the roles of CNVs, epigenetics, somatic mutations, and miRNA in CHD. Current technologies and strategies used to understand the genetics of congenital heart disease are also discussed. The chapter ends with an explanation of how these technologies can unravel the genetics of CHD and allow the application of research findings for the benefit of patients.

2. Classifications, anatomy, and clinical significance

Congenital heart disease encompasses a broad category of anatomic malformations, which can range from a small septal defect or leaky valve to a severe malformation requiring extensive surgical repair or leading to death such as a single ventricle. Several classification systems exist for describing congenital heart disease. The most common classification used to describe CHD is purely clinical whereby CHD is cyanotic if the malformation results in deoxygenated blood bypassing the lung and causes cyanosis (blue patient), or non-cyanotic if the malformation does not result in cyanosis. The most common cyanotic heart defects are Tetralogy of Fallot (TOF), Hypoplastic Left Heart Syndrome (HLHS), Transposition of the Great Arteries (TGA), Truncus Arteriosus (TA), and Total Anomalous Pulmonary Venous
Connection (TAPVC). Congenital heart defects can also be simple or complex. A complex malformation includes several simple malformations occurring together. The most typical example is Tetralogy of Fallot, which -as its name implies- includes four malformations: Pulmonary Stenosis (PS), an overriding aorta, Ventricular Septal Defect (VSD), and right ventricular hypertrophy. Because of the wide diversity in the anatomy of the cardiac malformations, several detailed morphological classifications were also developed. The most widely recognized one is the International Pediatric and Congenital Cardiac Code (IPCCC), which was developed by the International Society for Nomenclature of Paediatric and Congenital Heart Disease (ISNPCHD). Table 1 shows the categories of CHD classifications of the IPCCC with the most common diagnoses within each category. The detailed version could be downloaded from the IPCCC website (www.ipccc.net). Other classification systems are radiologic based on echocardiography or magnetic resonance imaging, hemodynamic based on shunts and circulations in the heart, or embryological based on the presumed origin during heart development. CHD can occur as part of a syndrome and as such is labeled as syndromic or nonsyndromic, both of which are discussed in this chapter. In syndromic and non-syndromic cases, CHD can be isolated, that is occurring in a single patient, or familial afflicting many members within the same family. The recurrence rate of CHD after an isolated case is 2.7%. (Gill and others 2003)

This anatomical heterogeneity of CHD has been one major reason why we know little about its genetics. Beyond the anatomical classification described in the IPCCC, different combinations of malformations and variations to described malformations can occur. Pediatric cardiologists often end up using different terminologies to describe similar defects because of their complexity. Extremely rare complex malformations are also sometimes described and run in families while their cause remains unknown.(Herrera and others 2008; Jaeggi and others 2008) Genotype-phenotype correlations are hard to establish due to this heterogeneity. In the majority of familial cases of CHD, there are different types of structural malformations within the same family. The same single gene mutation has been shown to cause a variety of cardiac defects, even within the same family.(Goldmuntz 2001) Whenever mouse knockout models were developed to recapitulate a human CHD phenotype, the mouse phenotype was not always similar to that seen in humans.(Bruneau 2008) All these issues raised the hypothesis of a multifactorial and perhaps polygenetic origin of CHD. The genetic background of the individual, in-utero environment, epigenetic changes, and embryological hemodynamics and physiology are all possible causes of this phenotypic heterogeneity.

Being a leading cause of deaths in the first year of life, CHD has prompted a large wave of development in surgical and interventional procedures to treat CHD. As such, CHD is mostly corrected with surgical and interventional procedures when the malformation causes symptoms or can cause heart failure such as a large septal defect or a cyanotic heart disease. Small malformations such as tiny septal defects that are expected to correct on their own or to not cause any complication are simply observed. With the recent advances in treatment, the mortality from CHD has decreased tremendously and most CHD patients survive a normal life throughout adulthood.(van der Bom and others 2011) This prompted a whole
new subspecialty in adult cardiology to take care of adult patients with CHD. (Moodie 1994)
As these adults with CHD are planning to have children of their own, the recurrence risk
became a problem, and this was yet another force to identify the genetic causes behind the
disease, given that genetic counseling and pre-implantation genetic diagnosis (PGD) can be
useful tools for these parents.

**Table 1.** IPCCC Classification of Congenital Heart Disease and Most Common Diagnoses
3. Developmental genetics of congenital heart disease

Heart development is crucial to understand because its molecular basis is evolutionary conserved as depicted by studies in several model organisms. Heart development is a complex process regulated by combinatorial interactions of transcription factors and their regulators, ligands and receptors, signaling pathways, and contractile protein genes among others. The differential expression of each of these genes at unique stages of development and in different areas of the heart is responsible for the normal development of the heart. Any disruption in these genes will result in congenital malformations of the heart. This molecular program for heart development has been a heavy field of research, yet our knowledge is far from being complete.

The heart is the first organ to develop in the embryo at the second week of gestation when pre-cardiac lateral plate mesoderm cells migrate towards the midline of the embryo and form two crescent-shaped primordia, which fuse to form a beating heart tube at week 3. Within only few days the heart tube folds on itself in a process known as looping. This is the first event in the organogenesis of the embryo that manifests left-right asymmetry and is believed to be at the origin of the laterality program of the embryo. Subsequently, the four chambers of the heart are formed. This requires the differentiation of myocytes into two different subtypes, atrial and ventricular. Finally, valves and septa form through divisions within the heart to form the mature four-chambered heart. Valvulogenesis and septogenesis both require interaction between endocardial and myocardial cells, and valvoseptal malformations are the most common CHDs. In addition, development of the conduction system occurs into pacemakers and purkinje cells, as well as vascularization from neural crest cells, and coronary arteries from epicardial precursor cells. As such, heart development requires a complex interplay of cell-commitment, migration, proliferation, differentiation, and apoptosis. Any perturbation in this program can result in congenital heart disease.

Transcription factors regulate this tight program of gene expression, which is chamber-, and stage-specific. Protein interactions and formation of complexes that regulate downstream targets cardiac targets with convergent and divergent pathways have made the understanding of the molecular basis of CHD complicated. In-vitro and in-vivo studies have been crucial in widening our understanding of the molecular program for heart development. Major transcription factor families involved in heart development include the GATA, T-box, homeobox, and basic Helix-Loop-Helix (bHLH) among others. Screening of human CHD patients for gene mutations within these transcription factor families as well as other cardiac-enriched genes implicated in heart development has not been as rewarding. Mutations in **TBX5, GATA4, NKX2-5** have been implicated in many CHD families and genetic tests became clinically available. Several other genes have been clearly established to cause syndromic cases of CHD such as **JAG1** and **ELN**. Deletions of chromosomal regions have also been established to cause several CHD syndromes, the most famous of which is DiGeorge Syndrome, which is caused by the 22q11.2 deletion. Despite all this progress, the majority of gene mutations
discovered in a family with CHD have not been confirmed in other families, or in only a few. Also screening of large cohorts of isolated CHD cases for mutations in a large set of cardiac-enriched candidate genes consistently results in a low yield of genetic causality.

This gap has prompted novel directions in understanding the genetics of CHD. One of the hypotheses is the multifactorial and polygenetic nature of CHD, with gene mutations acting on a certain genetic background or acting within a particular susceptible environment within a developmental window. There have been efforts towards a new systems biology approach to understanding CHD. In addition to germline DNA sequencing which comprises the majority of the literature, somatic DNA sequencing, RNA sequencing, study of microRNAs (miRNAs), and Copy Number Variations (CNVs) analysis are becoming more popular tools to study CHD. Also with the advent of next-generation sequencing and the decreased cost of both sequencing and array comparative genomic hybridization (array-CGH), more data are becoming available, and the molecular biology approach of the past few decades is shifting into a bioinformatics approach to help decipher the genetics of this complex disease. The subsequent sections of the chapter will dwell into the genetics of CHD from the oldest and most known to the most recent and least known. The below section discusses syndromic CHD, which comprises entities where the genetic causes is the most well established. Then the genes implicated in non-syndromic CHD in humans will be discussed with the degree of evidence for each. The most recent but least developed technologies to understand CHD mentioned above will be discussed at the end of the chapter.

4. Syndromic congenital heart disease

Cardiac malformations are among the most prevalent malformations in congenital syndromes. A large list of syndromes with congenital heart disease as a common manifestation has known genetic defects. CHD syndromes can be either due chromosome dosage disorders, large chromosomal deletions, small micro-deletions, or single gene defects. Table 2 shows a list of CHD syndromes within each of these categories with the corresponding genetic defect. This section will discuss the most common syndromes that include congenital heart disease as a primary manifestation. Within each syndrome, the phenotypic diversity as well as the spectrum of mutations and chromosomal defects that have been reported will be discussed.

4.1. Down Syndrome (trisomy 21)

Down Syndrome is the most common disorder of chromosome dosage with an incidence of 1 in 700 to 1 in 800 live births. The incidence is known to increase tremendously with increased maternal age, particularly above the age of 35. The main clinical manifestations of Down Syndrome are characteristic dysmorphic facies, mental retardation, premature ageing, congenital heart disease, hearing loss, and increased risk of hematologic malignancies. (Pueschel 1990)

Table 2. Syndromes Manifesting Congenital Heart Disease and their Genetic Cause

Congenital Heart Disease occurs in 40 to 50% of Down Syndrome patients. The most common abnormality is Atrioventricular Septal Defect (AVSD). (Marino 1993) Other malformations include VSD and TOF among others. Some CHD phenotypes are not seen in Down Syndrome patients such as Transposition of the Great Arteries (TGA) and Situs Inversus. (Marino 1993) Adult patients with Down Syndrome are also predisposed to Mitral Valve Prolapse (MVP) and fenestrations in the cusps of the aortic and pulmonary valves. (Hamada and others 1998)

Given the complexity of the phenotype in Down Syndrome, there has been tremendous effort to build a phenotype map and identify the genetic cause behind each phenotype. (Delabar and others 1993; Korenberg and others 1994) Although successful for other features of Down Syndrome, the cause of the cardiac malformations in Down Syndrome are still unclear. Knowing that CRELD1 gene mutations have been associated with AVSD, one screening of 39 Down Syndrome patients identified two missense CRELD1...
mutations and suggested that CRELD1 mutations might cause AVSD in Down Syndrome. (Maslen and others 2006) However other complex hypotheses have been suggested such as epigenetic mechanisms. Despite considerable progress for molecular genetic analysis of Down Syndrome has been achieved using mouse models, to date no clear cause for CHD is known.

4.2. Turner Syndrome

Turner syndrome is a condition in females where all or part of one sex chromosome is absent. It is estimated to occur in 1 of 2500 females. (Bondy 2009) It manifests most commonly with characteristic physical features such as short stature, webbed necks, broad chest, low hairline, and low set ears, gonadal dysfunction, and cognitive deficits. (Bondy 2009) Clinical features are highly variable and can sometimes be very mild. Congenital heart disease is found in 20% to 50% of Turner Syndrome patients. The most common malformation is a Coarctation of the Aorta (COA) of the postductal type, which comprises 50% to 70% of CHD in Turner Syndrome. (Doswell and others 2006) Other cardiac malformations seen in Turner Syndrome include Bicuspid Aortic Valve (BAV), Partial Anomalous Pulmonary Venous Connection (PAPVC), and Hypoplastic Left Heart (HLH). In addition, a higher frequency of cardiac conduction abnormalities, hypertension, and aortic dilation has been reported in Turner Syndrome patients. (Doswell and others 2006; Lopez and others 2008) The molecular mechanisms leading to the cardiac malformations in Turner Syndrome are not clear.

4.3. Di George Syndrome

Di George Syndrome (DGS) is also known as Velocardiofacial Syndrome (VCFS) or Chromosome 22q11.2 Deletion Syndrome. It is caused by a 1.5 to 3.0-Mb hemizygous deletion on chromosome 22 q11, which can be inherited in an autosomal dominant fashion, but most commonly arises de novo. (Emanuel 2008) The clinical manifestations are highly variable owing to incomplete penetrance. When the disease is fully penetrant, clinical manifestations include cardiac outflow tract defects, parathyroid gland hypoplasia resulting in hypocalcaemia, thymus gland aplasia resulting in immunodeficiency, and neurologic and facial abnormalities. (Emanuel 2008) Cardiac outflow tract defects in DGS include TOF, type B Interrupted Aortic Arch (IAA), Truncus Arteriosus, Right Aortic Arch, and aberrant right subclavian artery. (Momma 2010) (Yagi and others 2003) The molecular mechanisms leading to the phenotype in DGS are more known than for Down and Turner Syndromes. The microdeletion results in haploinsufficiency of the TBX1 gene, which is responsible for neural crest migration into the derivatives of the pharyngeal arches and pouches in the developing embryo. (Emanuel 2008) Target genes downstream of TBX1 are not yet elucidated, however they are most likely to explain the different phenotypes in DGS.

4.4. Williams-Beuren Syndrome

Williams-Beuren Syndrome (WBS) results from a hemizygous deletion of 1.5 to 1.8 Mb on chromosome 7q11.23, an area that encompasses 28 genes. Its prevalence is estimated to be 1
Genetic Causes of Syndromic and Non-Syndromic Congenital Heart Disease

in 7500. (Stromme and others 2002) Clinically, patients have Supravalvular Aortic Stenosis (SVAS), mental retardation, characteristic facial features, distinctive dental anomalies, infantile hypercalcemia, and peripheral pulmonary artery stenosis. (Beuren and others 1962; Grimm and Wesselhoeft 1980; Williams and others 1961) The cardiac phenotype of vascular stenosis is caused by haploinsufficiency of the Elastin (ELN) gene and is found in at least 70% of the patients. (Pober 2010) Mutations of the ELN gene also result in familial cases of SVAS without the syndromic features of Williams-Beuren. (Curran and others 1993; Metcalfe and others 2000) Although SVAS is the most common lesion in WBS patients, vascular stenoses can occur in any medium or large artery due to the thick media layer. Lesions have been described in aortic arch, descending aorta, pulmonary, coronary, renal artery, mesenteric arteries, and intracranial arteries. (Pober 2010) Half of Williams-Beuren patients also suffer from hypertension, and cardiovascular disease is the most common cause of death in these patients. (Pober 2010; Pober and others 2008)

4.5. Holt-Oram Syndrome

Holt-Oram Syndrome (HOS) is also known as Heart-Hand Syndrome, and it manifests as congenital heart disease and upper limb dysplasia. The heart manifestations are mostly septal malformations and include secundum ASD, VSD, patent ductus arteriosus, and conduction system abnormalities. The upper limb malformations are widely variable but are typically bilateral and asymmetric in severity. They can range from a small abnormality such as a distally-placed thumb to phocomelia or hypoplasia of the shoulders and clavicles. Sometimes the upper limb dysplasia can go unnoticed and will be seen only after radiological imaging. Congenital heart malformations occur in 85% of HOS patients. (Basson and others 1994; Boehme and Shotar 1989)

Genetically, HOS is an autosomal dominant disease caused by mutations in the TBX5 gene, a member of the T-box family of transcription factors. (Basson and others 1997; Li and others 1997b) Haploinsufficiency of TBX5 was shown to be at the origin of the HOS. TBX5 interacts with other cardiac-specific transcription factors GATA4 and NKX2-5 to regulate the expression of downstream genes such as ID2, which are essential in septation of the cardiac chambers as well as development of the conduction system. The functional mechanisms through which the three transcription factors TBX5, GATA-4, and Nkx2-5 interact to mediate processes in heart development have been heavily studied, and there is a very complex network of interactions among these and other transcription factors and downstream genes that exists but that is still partially understood (Figure 1).

Genotype-phenotype correlations were also performed in HOS, and it has been shown that TBX5 mutations that create null alleles result in more severe abnormalities in both upper limbs and the heart as compared to missense mutations. (Basson and others 1999) Some mutations caused very severe cardiac malformations but only subtle upper limb deformities. From a clinical perspective, it is important to look for subtle upper limb malformations in patients with septal deformities, because a diagnosis of HOS can increase the recurrence risk in a sibling from 3% to 50% given that this is an autosomal dominant disease. Clinical genetic testing for TBX5 has also become available in some laboratories across the world.
4.6. Alagille Syndrome

Alagille Syndrome is inherited in an autosomal dominant fashion and is defined in the presence of intrahepatic bile duct paucity that usually manifests as cholestasis, congenital heart disease, distinctive facies, skeletal, ocular, renal, and neurological abnormalities. (Kamath and others 2011; Li and others 1997a) CHD is found in more than 90% of patients with Alagille Syndrome and the most common lesion is Pulmonary Atery Stenosis (PAS) or hypoplasia. Other common lesions include TOF, pulmonary valve stenosis (PS), and ASD. (McElhinney and others 2002) The prevalence of the disease is estimated at around one in 700,000 neonates when presence of jaundice is used to ascertain cases (Danks and others 1977), but in fact the disease has a tremendous variability in the phenotype and variable penetrance in families so that the actual prevalence is expected to be much higher.

Alagille Syndrome is caused by mutations in the JAG1 gene. (Li and others 1997a; Oda and others 1997) The gene encodes a ligand to the Notch1 receptor. Jagged-Notch cell-cell interactions are crucial in determining cell fates during early developmental processes. The mutations spectrum of JAG1 in Alagille Syndrome encompasses frameshift mutations, nonsense mutations, splice site mutations, or deletion of the whole gene. (Yuan and others)
Mutations have also been identified in patients with a predominantly cardiac phenotype. Some families do have variable penetrance of the mutation as well as variant expressivity of the disease within the same family, such as facial dysmorphism only, or subtle liver disease only within members of the family carrying the same mutation. JAG-1 mutations are present in 94% of patients that are clinically diagnosed with Alagille Syndrome. A small number of cases are also explained by mutations in the Notch1 gene, the JAG-1 receptor.

Clinical testing for JAG-1 mutations is available. If patients are clinically diagnosed, a JAG-1 mutation could confirm the diagnosis, and indicate the need for multisystem assessment to look for other subclinical abnormalities and possibly prevent them. It would also allow for similar assessment of family members. Due to the high variability of the disease, patients with suspicious right-sided heart lesions such as PAS, TOF, and PS who do not necessarily fulfill the criteria for Alagille Syndrome could also be tested for JAG-1 mutations.

4.7. Noonan Syndrome

Noonan Syndrome (NS) is a dysmorphic cardiofacial syndrome inherited mostly in an autosomal dominant fashion, with some cases occurring sporadically. Its incidence ranges between 1 in 1000 to 1 in 2500 live births. The characteristic physical features are downward eyeslanting of the eyes, hypertelorism, low-set ears, short stature, short and webbed neck, and epicanthic folds. Congenital Heart Disease is found in 80 to 90% of patients with Noonan Syndrome and valvar pulmonary stenosis (PS) and Hypertrophic Cardiomyopathy (HCM) are the two most common cardiac manifestations. A large set of cardiac malformations can also occur including secundum ASD, AVSD, TOF, COA, VSD, PDA, and mitral valve disease. Patients might also have deafness, cryptorchidism, motor delay, and bleeding diathesis.

NS is a genetically heterogeneous syndrome with at least 8 genes that have been associated with the disease so far: PTPN11, SOS1, RAF1, KRAS, BRAF, MEK1, MEK2, and HRAS. Mutations in PTPN11 are most common and explain 50% of the Noonan Syndrome cases, the other 7 genes explain roughly 25% of the cases, and in about 25% of the cases no mutation is found. All the genes implicated in NS encode proteins that are part of the Ras/Raf/MEK/ERK signaling pathway, an important regulator of cell proliferation, differentiation, and survival. PTPN11 encodes SHP-2, a protein tyrosine phosphatase that plays an important role in the signal transduction to medial the biological processes described above.

Disease penetrance is almost complete with PTPN11 mutations, but there is a wide variability in the phenotype. Clinical testing for some of the genes involved in NS such as PTPN11, SOS1, and KRAS is available. Clinical diagnosis might be helpful might be helpful in borderline cases given the variability in the phenotype.
5. Nonsyndromic congenital heart disease

Isolated congenital heart disease is the most prevalent form of CHD. Evidence for the genetic basis of isolated CHD comes from familial clustering of cases as well as higher recurrence rate of CHD. Mutations in many genes have been associated with several CHD phenotypes, yet the evidence is variable for each gene. Gene mutations can best be classified as highly penetrant mutations in disease-causing genes, low-penetrance mutations in susceptibility genes, and common variants in CHD risk-genes. Transcription factor genes are the most common group of genes implicated in CHD. Other genes are part of signaling transduction pathways and structural components of the heart. Evidence for each gene comes from family studies and segregation analyses using direct sequencing. As mentioned earlier, one of the biggest challenges in the genetics of nonsyndromic CHD is that sequencing for all genes implicated in CHD explains the genetic cause of only a small percentage of patients. Most gene mutations have been described in one or few cases, while only a small number of genes have been duplicated in many cohorts and families.

Table 3 lists all genes in which mutations have been found in different nonsyndromic CHD phenotypes. Most of these are based on only few cases and hence remain to be ascertained; however some have been duplicated in several families such as the phenotypes associated with NKX2-5 or GATA4 mutations. The table lists all the genes in which mutations have ever been described for each phenotype. The corresponding PubMed IDs are provided for the published studies where these gene mutations are reported so that readers can make their own assessment regarding the strength of the association.

</table>
In the remaining part this section, the most common genes implicated in nonsyndromic CHD are discussed in details. For each gene, the mutational spectrum, function, associated CHD phenotypes, and mechanism of disease (if known) are provided. The three large groups of cardiac specific transcription factors, the GATA (\textit{GATA4, GATA5, and GATA6}), Homebox (\textit{Nkx2-5 and Nkx2-6}), and T-box (\textit{TBX1, TBX5, and TBX20}) are first discussed in detail each in a separate subsection. These three categories of genes comprise the majority of the known genetic causes of CHD. Genes from all three categories interact to regulate downstream gene expression in the developing heart. Other transcription factor genes are discussed in a separate section. Different signaling pathway genes such as the NODAL signaling genes and the Notch signaling pathway are discussed separately. Contractile protein genes, in addition to their well-established role in cardiomyopathy, have been associated with CHD and are mentioned under one section. All remaining genes with minimal evidence for causing CHD comprise are clustered under the final subtitle of this section of the chapter.

### 5.1. GATA transcription factors (\textit{GATA4, GATA5, GATA6})

GATA-binding proteins are a family of transcription factors that regulate gene expression and are involved in cell differentiation, survival, and proliferation in many tissues. GATA proteins are evolutionary conserved proteins containing two zinc-finger motifs. They recognize and bind to a “GATA” consensus sequence, which is an important \textit{cis}-element of the promoters of many genes.

\textit{GATA4, GATA5, and GATA6} are involved in the developing heart, and knockout studies in mice have shown that all three are essential for normal cardiac development. Silencing of GATA genes can result in cardiac malformations ranging from valvoseptal defects to acardia. However, mutations in humans with CHD have been described only in \textit{GATA4} and \textit{GATA6} but not \textit{GATA5}.

\textit{GATA} genes are also among the earliest transcription factors to be expressed in the developing heart. They are expressed in different but overlapping time and tissue patterns in the embryonic heart and manifest complex combinatorial interactions. These characteristics seem to be essential for proper embryonic and postnatal cardiac development.

\textit{GATA4} mutations are a well-established cause of CHD in humans. They are inherited in an autosomal dominant fashion in familial cases and are also seen in isolated cases. Haploinsufficiency of the \textit{GATA4} gene causes CHD, which is highly penetrant as observed...
in familial studies. The most common phenotypes were causative \textit{GATA4} mutations are found are ASD, VSD, TOF, and AVSD.\cite{Garg2003, Nemer2006} Findings of \textit{GATA4} mutations have been duplicated in many familial studies.\cite{Chen2010, Garg2003} Multiple phenotypes are often seen within the same family segregating the same mutation. In isolated studies of CHD cohorts with phenotypes within the spectrum of phenotypes obtained from \textit{GATA4} knockout mice, the frequency of \textit{GATA4} mutations ranges between 0.8\% and 3.7\%.\cite{Peng2010, Rajagopal2007, Tomita-Mitchell2007, Zhang2006} The spectrum of mutations in \textit{GATA4} includes missense mutations as well as mutations that truncate the protein such as nonsense, frameshift, or splice site variants. Disease-causing missense mutations often disturb the cooperative binding of \textit{GATA4} to other transcription factors such as \textit{Nkx2-5} and \textit{TBX5} (Figure 1), a process which is essential for modulating downstream gene expression during cardiac development.

Animal studies have shown that while \textit{Gata4}^{+/-} and \textit{Gata6}^{+/-} mice survive normally, compound heterozygous \textit{Gata4}^{+/-} \textit{Gata6}^{+/-} mice die at embryonic day 13.5 due to severe cardiac malformations.\cite{Xin2006} Also when both genes are knocked out completely, mice fail to develop any heart.\cite{Zhao2008} These studies have shown that both \textit{Gata4} and \textit{Gata6} are essential for cardiac development and that they interact to regulate downstream targets during heart development. Inactivating \textit{Gata6} in specific vascular cells using transgenic mice has also shown that \textit{Gata6} is involved in the migration of neural crest cells and differentiation of terminal smooth muscle cells, late processes in cardiac development.\cite{Lepore2006} Sequencing of patients with CHD corroborated animal findings by identifying heterozygous \textit{GATA6} mutations in outflow tract defects, mainly Common Arterial Trunk (CAT).\cite{Kodo2009} Subsequent studies showed that \textit{GATA6} mutations also cause ASD and TOF.\cite{Lin2010} Like for \textit{GATA4}, the mutational spectrum of \textit{GATA6} includes missense as well as truncating variants, and genotype-phenotype correlations are not established as the same mutation can cause different phenotypes. In many laboratories around the world, clinical genetic testing is commonly available for \textit{GATA4}, but not for \textit{GATA6}.

### 5.2. Homeobox transcription factors (\textit{NKX2-5}, \textit{NKX2-6})

Homeobox-containing genes are transcription factors that play crucial roles in cardiac development through regulating essential processes such as the spatio-temporal specificity of gene expression required for normal cardiac tissue differentiation. This transcription factor is evolutionary conserved and essential for cardiac development. The “\textit{Tinman}” gene in drosophila is a homeobox-containing gene that is essential for development of the dorsal vessel, a structure analogous to the human heart. \textit{NKX2-5} is the “\textit{Tinman}” homologue in mouse and is highly expressed in the mouse embryologic heart and essential for its development.\cite{Reamon-Buettner2010} The \textit{NKX2-5} gene was cloned in 1996 \cite{Turbay1996}, and since then it was shown to be one of the most common known genetic causes of human CHD.
Mutations in Human Genetic Disease

NKX2-5 plays critical roles in later stages of cardiac development, namely septation and development of the conduction system. It physically interacts with TBX5 to form a complex that cooperatively regulates downstream gene expression that is essential for proper septation and formation of the conduction system. (Habets and others 2002; Moskowitz and others 2007) Mutations in NKX2-5 gene cause congenital heart disease in an autosomal dominant fashion and with high penetrance. (Kasahara and others 2000) Many families have been described. The most common phenotype is ASD with Atrioventricular (AV) Block. However NKX2-5 mutations have also been associated with many other CHD phenotypes such as VSD, TOF, subvalvar AS, Ebstein’s Anomaly, cardiomyopathy, ventricular hypertrophy or non-compaction, and arrhythmias other than the common AV block. (Reamon-Buettner and Borlak 2010) Also in families, different CHD phenotypes can be observed with the same NKX2-5 mutations making genotype-phenotype correlations difficult. In cohorts of isolated CHD, NKX2-5 mutations are found in around 2%. (Reamon-Buettner and Borlak 2010) The mutational spectrum is wide with missense and truncating mutations being heavily described. Sequencing for NKX2-5 is clinically available for genetic testing. Identifying family members through cascade screening might allow the diagnosis of fatal arrhythmias or silent ASD’s that can otherwise lead to heart failure.

NKX2-6 is another homeobox transcription factor that shares great homology with NKX2-6 but whose downstream targets are unknown. Mouse in which NKX2-6 was knocked out did not have any cardiac phenotype, but one mutation has been associated with CAT in one family. (Heathcote and others 2005) More mutations in NKX2-6 remain to be detected in CHD patients with high throughput screening before its causality to CHD could be established.

5.3. T-Box transcription factors (TBX1, TBX5, TBX20)

The T-box family of binding proteins also consists of important transcription factors in cardiac development. T-box genes are evolutionary conserved and share a T-binding domain. All family members are involved in regulating developmental processes such as the initiation and potentiation of cardiac development. (Hariri and others 2011)

The crucial role of TBX5 in heart development and its interactions with GATA4 and NKX2-5 has been discussed earlier in this chapter. Apart from Holt-Oram Syndrome, TBX5 has not been implicated in nonsyndromic CHD, although some TBX5 mutations can cause a heart-predominant phenotype with very subtle upper limbs disease. TBX1 was also discussed earlier as the cause of cardiac malformations in Di George Syndrome. A large deletion of 57bp in the TBX1 gene was found in one non-syndromic patient with TOF. (Griffin and others 2010) Apart from this single report, findings of TBX1 mutations have not been duplicated in non-syndromic CHD patients.

Another member of the family that has been implicated in non-syndromic CHD is TBX20. Tbx20-/- mice have dilated cardiomyopathy and TBX20-/- mice die at midgestation due to grossly abnormal heart. (Stennard and others 2005) Mutations in TBX20 are found in less than 1% of patients with CHD phenotypes such as septal defects, left ventricular outflow
tract abnormalities, and HLH syndrome. (Kirk and others 2007; Posch and others 2010) Both missense and nonsense heterozygous mutations are described. Functional studies suggest that both loss of function and gain of function mutations in the TBX20 gene can cause CHD. (Posch and others 2010)

5.4. Other transcription factors (CITED2, ANKRD1, FOG2, ZIC3)

The above three families of transcription factors are the most heavily studied in heart development, however a large set of other transcription factors have also been implicated in CHD, yet with lower degrees of evidence, or for some lower penetrance. This section will briefly discuss each of these transcription factors.

CITED2 codes for CBP/p300-Interacting Transactivator with E/D-rich c-terminal Domain Type 2, a transcriptional co-activator several transcriptional responses such as TFAP2, the known cause of Char Syndrome. CITED2 null mouse embryos die embryologically and manifest septal, outflow tract, and aortic arch defects. (Bamforth and others 2004) CITED2 mutations were detected in about 1% of sporadic cases of CHD. Phenotypes include ASD, VSD, and TAPVC. (Sperling and others 2005)

Ankyrin Repeat Domain 1 (ANKRD1) is a transcription factor that interacts with cardiac sarcomere proteins. One balanced translocation and one missense mutation in ANKRD1 gene were detected in two separate cases of TAPVC. (Cinquetti and others 2008)

Friend of GATA 2 (FOG2) is, as its name implies, a cofactor of GATA4. FOG2 knockout mice have TOF-like phenotype, (Tevosian and others 2000) and FOG2 mutations have been described in TOF patients however with reduced penetrance. (Pizzuti and others 2003)

ZIC3 encodes for a zinc finger transcription factor that is implicated in left-right axis development. It is a known gene in human situs abnormalities and is inherited in an X-linked fashion. Mutations in ZIC3 have been identified in families and cohorts of heterotaxy. (Gebbia and others 1997) Additionally, there has been one reported family with TGA carrying a transversion in the ZIC3 gene, yet with incomplete penetrance. (Megarbane and others 2000)

5.5. NODAL signaling genes (NODAL, GDF1, FOXH1, CFC1, ACVR2B, LEFTY2)

The NODAL family of proteins is member of the TGF-beta superfamily of secreted signaling molecules. NODAL signaling is responsible for dorso-ventral patterning in vertebrate development as well as mesoderm and endoderm generation. Mutations in different genes in the NODAL signaling cascade are believed to occur and cumulatively decrease NODAL signaling leading to CHD phenotypes. (Roessler and others 2009) NODAL mutations have been reported in patients with heterotaxy, TGA, and conotruncal defects. (Gebbia and others 1997; Mohapatra and others 2009) but as mentioned earlier simple heterozygosity is not
enough to cause the phenotype in the majority of cases. Mutations in other pathway genes such as \textit{GDF1, FOXH1, CFC1,} and \textit{LEFTY2} are often necessary to cause disease.

\textit{CFC1} (Cryptic) is a cofactor of NODAL signaling and its acts through activin receptors. \textit{CFC1} mutations have been initially reported in laterality defects.\cite{Bamford2000} However, outflow tract defects such as TGA and DORV have also been associated with \textit{CFC1} mutations.\cite{Goldmuntz2002} Similar associations with CHD phenotypes apart from \textit{situs} abnormalities have been observed for \textit{GDF1, another member of the TGF-beta superfamily involved in NODAL signaling.}\cite{Karkera2007} \textit{FOXH1} mutations have been associated with CHD however only within the context of reduced NODAL signaling due to mutations in more than one gene in the cascade.\cite{Roessler2008} Therefore, sequencing of all NODAL signaling genes together would give a better picture of the genetic cause of a particular CHD phenotype rather than identifying a variant in one of the genes.

5.6. Notch signaling genes (\textit{NOTCH1, JAG1, NOTCH2})

The Notch-Jagged signaling pathway is an important regulatory mechanism of cell differentiation processes during embryonic and adult life. In the heart, it is particularly important in cardiac valve development. \textit{JAG1} and \textit{NOTCH2} mutations are known causes of Alagille Syndrome. However mutations in both can cause non-syndromic CHD.\cite{Bauer2010, McDaniell2006} \textit{NOTCH1} has been also implicated in non-syndromic CHD. Mutations can cause BAV, AS, COA, and HLH.\cite{Garg2005, McBride2008, Mohamed2006}

5.7. Contractile protein genes (\textit{MYH6, MYH7, MYH11, MYBPC3, ACTC1})

Mutations in contractile protein genes are common causes of Hypertrophic Cardiomyopathy (HCM) and other cardiomyopathies. However, some of these genes have also been implicated in a minority of CHD cases. One \textit{MYH6} (Alpha Myosin Heavy Chain) mutation has been described in a family with ASD.\cite{Ching2005} Mutations in \textit{MYH7} (Beta Myosin Heavy Chain) can cause Ebstein’s Anomaly and septal defects.\cite{Budde2007} Heterozygous \textit{MYBPC3} mutations are a very frequent cause of HCM, however there have been reports of ASD and PDA in addition to severe HCM in patients with homozygous truncating mutations in the Myosin Binding Protein C gene \textit{MYBPC3}.\cite{Xin2007, Zahka2008} Similarly, mutations in Alpha-Cardiac Actin \textit{ACTC1}, another sarcomere protein gene, cause ASD together with HCM.\cite{Monserrat2007} Finally, Myosin Heavy Chain 11 (\textit{MYH11}) has a role in smooth muscles, and mutations in \textit{MYH11} have been implicated in familial thoracic aortic aneurysm with PDA due to decreased elasticity of the aortic wall and the ductus arteriosus.\cite{Zhu2006}

5.8. Miscellaneous genes (\textit{ELN, GJA1, FLNA, THRAP2})

Elastin (\textit{ELN}) deletion or mutations are implicated in Williams-Beuren syndrome, however have also been reported in many cases of isolated SVAS and PS.\cite{Arrington2006;
Metcalfe and others 2000) GJA1 encodes Connexin-43, a gap junction protein that maintains cell-cell adhesion and communication. Mutations in GJA1 were reported in a case of HLH and another report of heterotaxia patients. (Britz-Cunningham and others 1995; Dasgupta and others 2001) Filamin A (FLNA) cross-links actin filaments in the cytoplasm and anchors them to the rest of the cytoskeleton. FLNA is an X-linked gene in which mutations are associated with valvular dystrophy. (Kyndt and others 2007) Finally, mutations in the THRA32 gene, which encodes a TRAP-complex protein, have been associated with TGA in one study. (Muncke and others 2003)

6. Other genetic mechanisms of CHD

Despite the large number of genes implicated in non-syndromic CHD, the genetic cause of the majority of isolated cases of CHD is still poorly understood. This has led researchers to investigate genetic mechanisms other than gene mutations that can contribute to inherited or isolated CHD. Copy Number Variations (CNVs), micro RNA (miRNA), somatic mutations, and epigenetics are all active areas of research into the genetics of CHD.

6.1. Copy Number Variations

Copy Number Variations (CNVs) are structural alterations to the genomic DNA that result in the cell having abnormal copies of large sections of its DNA. They can be inherited or occur de novo. Over the past decade, the role of CNVs in disease has been heavily studied, mostly in different types of cancers. In the heart, CNV analysis has explained an additional small fraction of the genetics of syndromic CHD (3.6%), but more of the non-syndromic CHD (19%). (Breckpot and others 2011) Submicroscopic deletions have been discovered using array-CGH in large CHD cohorts. CNVs occurred in regions harboring known CHD candidate genes but were also capable of identifying new CHD loci in TOF, HLH, heterotaxy, and other CHD phenotypes. (Fakhro and others 2011; Greenway and others 2009; Payne and others 2012) One of the most commonly used strategies in CNV analysis is trio analysis, which allows the determination of de novo CNVs in CHD patients. Comparison with control groups is also helpful in assessing the likelihood of causality of CNVs using statistical methods. Despite several successful examples, the use of CNVs in understanding CHD remains challenging, particularly in proving the causality of the CNVs and assessing the magnitude that these CNVs have on the phenotype.

6.2. Micro RNA

Micro RNAs (miRNAs) are small (around 22 nucleotides long) single stranded noncoding RNAs and are encoded by miRNA genes. miRNAs serve as regulators of gene expression. Since cardiac development involves tremendous spatio-temporal specificity of gene expression, it is believed that miRNAs are involved in cardiac development and they can potentially cause CHD. miRNAs are important players in cellular proliferation, differentiation, and migration all of which are essential processes for proper cardiac
development. In fact, cardiac specific miRNAs were discovered such as miR-133 and miR-1-2, both of which when knocked out in mice cause cardiac defects, specifically VSD and dilated cardiomyopathy. (Ikeda and others 2007) miR-208a and miR-208b are also cardiac-enriched, and they are encoded within the introns of MYH6 and MYH7. (Callis and others 2019; van Rooij and others 2007) Current research focuses on sequencing miRNA to identify potential mutations that can cause CHD. Definite evidence in humans is still unavailable but might be underway.

6.3. Somatic mutations

Another direction of research to assess CHD is the study of somatic mutations using surgically discarded tissues from CHD patients who undergo surgical repair. Both DNA and RNA can be extracted and sequenced. Previous studies have focused on sequencing GATA4 and Nkx2-5 in somatic DNA of patients with septal defects, and yielded controversial findings as to whether somatic mutations contribute significantly to these genes. (Draus and others 2009; Esposito and others 2011; Reamon-Buettner and Borlak 2004) In the current era of high throughput DNA sequencing, and development of new analytical frameworks for RNA sequencing, the contribution of somatic mutations to CHD will become clearer soon, however no significant data in this field is published yet.

6.4. Epigenetics

The multifactorial causality of CHD has long been hypothesized to explain the complexity of the genetics of cardiac malformations. Epigenetics is one model where gene-environment interaction can affect gene expression and disturb developmental processes in the embryonic heart. Histone modifications and chromatin remodeling both play important roles in cardiac development and physiology (Han and others 2011; Lange and others 2008; Ohtani and Dimmeler 2011), and recent studies showed that they can directly interact with some classes of transcription factors like the T-box family. (Miller and Weinmann 2009) It is possible that epigenetic mechanisms contribute to the etiology of CHD, however more evidence remains to be established.

7. Current tools for the genetic evaluation of CHD

Different techniques are currently available to interrogate the genetic causes of CHD. Karyotyping and Fluorescent In-Situ Hybridization (FISH) analysis remain the best tools to assess chromosomal deletions or rearrangements. They are often the starting point for the genetic assessment of a CHD patient. Whenever candidate genes are suspected, for instance in the setting of a clinically diagnosed syndrome, Sanger sequencing is performed on the candidate gene to look for disease-causing mutations. For many years, together with positional mapping through linkage analysis, these were the only tools that drove genetic discovery in CHD in humans. Current technology makes use of array-comparative genomic hybridization (array-CGH) for linkage analysis, Genome Wide Association Studies (GWAS), CNV analysis, homozygosity mapping, and transcriptome analysis. More
importantly was the introduction of next-generation sequencing in 2005 and the tremendous decrease in the cost of sequencing over the past several years, which is allowing the massive sequencing of the exome and even genome of huge numbers of patients. Next-generation RNA sequencing is also beginning to be used to sequence cardiac transcripts from CHD patients who have underwent surgery. The rapid pooling of high throughput data is expected to massively increase our understanding of CHD within the coming two years. To deal with these large amounts of data, bioinformatics and modeling of genetic variants determine function is becoming the standard and many molecular biology labs are forced to become genetics and bioinformatics labs to make use of current technology. A systems biology approach is needed nowadays to integrate high throughput data from the many possible sources.

8. From the bench to the bedside

With the advances in sequencing and bioinformatics, gene discovery in CHD is escalating. This advance in research is directly translated to clinical testing to provide genetic counseling for adult patients with CHD who plan to have children. From a technical aspect, our capability to identify genetic variants in CHD genes has magnified. Nonetheless, making functional significance and even clinical sense of the large number of gene mutations remains a big challenge. Given the complexity of CHD, definite gene mutations remain uncommon. At this time when the genetic inflow of information is very fast, physician-scientists must be very careful in communicating genetic information that is not validated to patients, in order to avoid psychological and emotional harm. On a different angle, with sequencing of the exome or genome, the chances of detecting incidental findings that indicate disease risk or prognosis becomes very high. All such unintentionally detected serious genetic findings are termed the incidentalome.(Kohane and others 2006) Since CHD is mostly surgically treated and people who undergo genetic testing are often already cured, caregivers need to be cautious before rushing next-generation sequencing into the CHD clinic.

9. Future prospects

Current trends in CHD genetics research are making use of the rapidly developing technology, particularly high throughput sequencing. This trend will continue over the coming few years. The challenge is in integrating the increasing amounts of data to answer the questions that need to be answered. Systems biology and innovative bioinformatics tools are crucial to integrate data from different sources and build a pipeline that can unravel the mysteries that molecular biologists have been trying to answer for many years.

Eventually, more validated genetic information will be available in the clinic to allow accurate genetic counseling and prenatal screening. Understanding heart development will also allow for possible therapeutic applications given the many-shared molecular pathways between embryologic heart development and adult heart disease, particularly tissue death and regeneration in the setting of ischemic heart disease.
