Chapter 4

Self-Assembly of Copper Oxide Core-Shell Nanowires Through Ethyl Alcohol

Sheng Yun Wu

Additional information is available at the end of the chapter

http://dx.doi.org/10.5772/52584

1. Introduction

The control of the core-shell structure at the nanometer is one of the most fundamental challenges in condensed matter science [Deville et al., 2009; Woodley et al., 2008; Bannin, 2007; Ji et al., 2007; Lauhon et al., 2002]. One of the fundamental concepts regarding the synthesis of nanowires via the spontaneous self-organization of individual nanoparticles, called spontaneous organization nanocrystals, refers to the formation of two-dimensional (2-D) and 3-D arrays of nanoparticles or nanowires [Tang et al., 2002; Lu et al., 2002; Balazs et al., 2006; Tang et al., 2006]. The copper-oxide based system, such as Cu$_2$O [Huang et al., 2012; Hong et al., 2011; Yao et al., 2010], CuO [Wu, 2012; Cheng et al., 2007; Chou et al., 2008], and Cu$_2$O@CuO [Yec et al., 2012], has been known to facilitate oxidation reactions in the bulk material, which may allow it to be a cost effective substitute for noble metals in various catalytic systems. With recent developments in nanostructures synthesis leading to the ability to control size, reproducibility and structural complexity [Lauhon et al., 2002; Fan et al., 2006; Lu et al., 2005], it becomes worthwhile and possibly paramount to define specific target structures for the nanoparticles based on an understanding of the mechanism of the self-organization mechanism. Upto now, many complex procedures, such as vapor-liquid-solid, chemical vapor deposition, thermal evaporation, and chemical reactions, have been developed for the synthesis of one-dimensional materials of Copper-based nano compounds [Huang et al., 2012; Hong et al., 2011; Yao et al., 2010]. In addition to these methods, solution chemical route including solvothermal, hydrothermal, self-assembly, and template-assisted chemical vapor deposition has become a promising option for large-scale production of nanomaterials, due to the simple, fast, and less expensive virtues [Xin et al., 2002; Li et al., 1999; Lu et al., 2000; Hung et al., 2004; Roy et al., 2003; Baxter et al., 2003]. However, a new type of immersing nanoparticles into liquid alcohol
to form core-shell nanowires at room temperature has been difficult, primarily because control
of nucleation and growth is still a challenge.

In the present work, we report on a simple method for bottom-up fabrication by means
of template-free growth of high density Cu$_2$O/CuO core/shell nanowires. These can be
spontaneously self-assembled by the oxidation of ultra-small copper nanoparticles simply
immersed in ethyl alcohol. This leads to the formation of Cu$_2$O/CuO core/shell nano-
wires. Then nanosized growth effects of these nanowires are observed experimentally.
We find that the formation of nanowires may be far more due to chemical reactions than
previously realized.

2. Synthesis method

The initial Cu nanoparticles used as a precursor in the synthesis of Cu$_2$O/CuO core/shell nano-
wires, are fabricated by employing the gas condensation method, as shown in Fig. 1. High puri-
ty Cu ingots (~ 0.5 g, 99.999% pure and 3 mm in diameter) are heated by a current source of 90 A.
They are evaporated at a rate of 0.01 Å/s in an Ar pressure of 0.1 Torr. The evaporated Cu nano-
particles are collected on a non-magnetic quartz plates (1 cm x 1 cm), maintained at liquid nitro-
gen temperature. After restoration to room temperature, the nanoparticles, which are only
loosely attracted to the collector, are stripped off. The resultant samples were in the form of
dried powder, consisting of a macroscopic amount of individual Cu nanoparticles. The com-
bined effect of high gas flow rate, low deposition pressure and relatively low substrate temper-
ature resulted in the deposition of copper nanoparticles. The moving Cu nanoparticles were
washed and stripped off from quartz plates using ethyl alcohol(99.5%) in argon gas environ-
ment (chemical hood), as shown in Fig. 2(a). They were then kept in a glass container and in a
sealed quartz capillary (Fig. 2(b) and 2(c) for few days) for in situ x-ray scattering examination.
The sample is apparently not sensitive to being exposed to air for a short period of time, which
is supported by the fact that the x-ray diffraction patterns of the as-grown sample and sample
exposed to air for few hours are indistinguishable. However, the sample used in the study is
kept in glass container with liquid alcohol. The main key method for sample syntheses in this
study was that the ethyl alcohol solution-phase was important to fostering spontaneous
growth of Cu nanoparticles which then led to the formation of Cu$_2$O/CuO core/shell nanowires
at room temperature. In general, metal-oxide nanowires can be synthesized using a solid-state
method involving high temperature oxidation of the metal [Cheng et al., 2007; Devan et al.,
2008] and a solution-phase under hydrothermal conditions [Tan et al., 2007]. However, a typi-
cal reaction requires very high temperature or pressure and therefore would seem to be incom-
patible with our system [Yang et al., 1998]. Copper oxide nanoparticles in a limited size range
have been prepared with other techniques using chemical routes, and some of these techniques
have resulted in alimited growth of rodlikenanocrystals reported by Fang group [Fang et al.,
2004]. Ethyl alcohol (CH$_3$-CH$_2$OH) is chosen as the reactive solution for the spontaneous orga-
nization method, because of its dipole moment (1.684 Debye), which is comparable to that of wa-
ter (1.69 Debye), and its polar character, which allows the formation of Cu$_2$O/CuO core/shell
nanowires with an alcohol bridge. In the presence of a rich OH$^-$ solution, spontaneous oxida-
tion can be drastically accelerated. This procedure has been reported by Tello and coauthors [Tello et al., 2003] for the oxidation of $p$-silicon in water and ethyl alcohol. They demonstrated that local oxidation in liquid ethyl alcohol environments is different from that in aqueous solutions, with a significant improvement in the growth rate. The Liu group [Liu et al., 2009] also reported that the dosage rate can influence the morphologies of Cu$_2$O, so that the shape of the nanostructures can be controlled through adjusting the reduction rate of Cu$^{2+}$ ions. In this study, Cu$^{2+}$ ions are released continuously from the copper nanoparticles into the ethyl alcohol under ambient conditions. These can be immediately captured through coordination with OH$^{-}$ to form Cu(OH)$_2$. After 4-days ($D=4$) of immersion, the Cu(OH)$_2$ loses water and CuO or Cu$_2$O is formed by the release of O$_2$. The resultant copper-based phases can be either cuprous oxide or cuprite oxide depending on the temperature and surrounding environment. At room temperature, however, the cuprous phase is the dominant product of oxidation. The cuprous surface can be terminated by a few mono layers of cuprite oxide product (crystalline or amorphous phase) at the solution interface, forming Cu$_2$O/CuO core-shell nanowires. The prepared samples were mounted in a capillary rotor sample holder and the process of the formation of nanowires was systematically studied using an in situ x-ray diffractometer (Philips X’Pert PRO) with CuK$_\alpha$ radiation ($\lambda=1.541$ Å) at times ranging from one to seven days. The morphology of sample was characterized by a field emission scanning electron microscope (FE-SEM, JEOL JSM-6500F) equipped with an energy dispersive x-ray spectroscope (EDS, Oxford Instrument INCAx-sight 7557). Atomic-resolution transmission electron microscopic (TEM) analysis and high-resolution transmission electron microscopy (HRTEM) images were taken with the CCD-camera of an electron microscope (JEOL JEM-2100) at 200 kV. Analysis software (Digital Micrograph) was employed to digitalize and analyze the obtained images.

3. Results and discussion

The in situ x-ray diffraction patterns at various time periods were shown in Fig. 3. As indicated on the bottom of Fig. 3, there are three nuclear peaks at the {1 1 1}, {2 0 0} and {2 2 0} positions, as indexed based on a cubic Cu -Fm-3m structure, with a lattice expansion of ~1.5 % compare with Cu bulk. According to the Scherrer diffraction formula, the average size of initial Cu nanoparticles can be described as:

\[
\frac{(\Delta 2\theta_B)}{\tan^2 \theta_B} = \frac{\lambda}{<d> \times \Delta 2\theta_B} \tan \theta_B \sin \theta_B + 16\epsilon^2,
\]

where <d> is the mean size, \( \lambda (=1.541 \text{ Å}) \) is the incident x-ray and \( \Delta 2\theta_B \) is FWHM at the scattering angle of 2\( \theta_B \). The obtained mean size of Cu nanoparticles is <d>=5.4 nm, estimating from these peaks in the diffraction pattern. After immersion in an ethyl alcohol solution four days, we observe a significant broader peak around \( 2\theta=36^\circ \), which is associated with the CuO structure of the Miller index {1 1 1}, and exhibits the coexistence of core/shell nanocrystals. This may be understood by assuming the existence of the CuO phase near the surface, with the oxidation contribution coming from the Cu atoms in the core. The pattern in the upper part of Fig. 3 should contain, in principle, contributions from the CuO phase, after 7-days (D=7) of immersion. X-ray diffraction patterns are known as the fingerprints of crystalline materials. They reveal details of the crystalline structure and their formation during synthesis, and even the
crystalline phase transitions or separation at various temperatures. An example of x-ray and Rietveld refined diffraction patterns of the sample, taken at D=7, is shown in Fig. 4. Diffraction patterns were utilized to characterize the crystalline structure in the prepared samples. The diffraction peaks appeared to be much broader than the instrumental resolution, reflecting the nano-size effects. The analysis was performed using the program package of the General Structure Analysis System (GSAS) [Larson et al., 1990] following the Rietveld method [Rietveld, 1969]. Several models with different symmetries were assumed during the preliminary analysis. In our structural analysis we then pay special attention to searching for the possible symmetries that can describe the observed diffraction pattern well. All the structural and lattice parameters were allowed to vary simultaneously, and refining processes were carried out until $R_p$, the weighted $R_{wp}$ factor, differed by less than one part in a thousand within two successive cycles. Figure 4 shows the diffraction pattern (red crosses) taken at room temperature, where the solid curve (green curve) indicates the fitted pattern and the difference (pink curve) between the observed and the fitted patterns is plotted at the bottom of Fig. 4. The refined lattice parameters are $a=b=c=4.2821(5)$ Å with a space group of Cu$_2$O-Pn-3m structure. The formation of Cu$_2$O requires an expansion of only 0.026 % of the metallic Cu nanoparticles to make room for the O atoms, comparing with Cu$_2$O bulk ($a=4.281$ Å). The decrease in surface energy of the nanowires will tend to cause an increase in their size by elastic distortion of their crystal lattice. Of course, this kind of distortion is very small compared to the whole particle size. It is worth noting that the contribution of the intensity of the CuO shell (as can not be seen in the x-ray patterns) is undetectable or amorphous in state. These characteristics (i.e., the amorphous CuO shell) agree with previously reported results for Cu$_2$O/CuO nanoparticles obtained by Yin et al. [Yin et al., 2005]. In their comprehensive analysis, they found that Cu nanocrystals formed initially, but were subsequently oxidized to form a highly crystalline Cu$_2$O coated with an amorphous epitaxial CuO layer.

Figure 3. In situ time dependence of x-ray diffraction patterns taken at room temperature.
The morphology of selected samples at D=1, 4 and 7, was characterized by FE-SEM, as shown in Figs. 5(a) to (c). As can be seen in Fig. 5(a), it is clearly evident that the nanoparticles are spherical and stick together due to an electrostatic effect as well as an artifact of the drying of aqueous suspensions. It can be seen that the Cu$_2$O/CuO nanowires grew homogeneously in a large area to form straight nanowires, as shown in Fig. 5(b). The diameters ranged from 100-500 nm and the lengths were up to several tens of microns. As can be seen in Fig. 5(c), the Cu$_2$O/CuO core-shell nanowires are long and straight, ranging from tens of micrometers to more than a hundred micrometers. The growth of the nanowires is clear. An evaluation of the diameter distribution can be obtained and calculated from a portion of the SEM image, as shown in the Figs. 5(d) to 5(f). They are quite asymmetric and can be described using a log-normal distribution function defined as follows:

$$ f(d) = \frac{1}{d \sigma \sqrt{2\pi}} \exp \left( -\frac{(\ln d - \ln <d>)^2}{2\sigma^2} \right), $$

where $<d>$ is the mean value and $\sigma$ is the standard deviation of the function. The mean diameters and standard deviations for the nanowires obtained from the fits are $<d>=201(5)$ to 225(5) nm, $\sigma=0.42$ and 0.31 nm at D=4 and 7, indicating increasing diameter as the reaction time increases. The small standard deviation ($\sigma<0.5$) of the function indicates that the distribution is confined to a limited range. It can be seen that the width of the distribution profile broadens due to the crystalline structure. The stability of growth during the formation of core-shell nanowires is confirmed by examination of the SEM images even at D=240 (not shown). This result indicates that increasing the reaction time by immersion in ethyl alcohol cannot make the growth of diameter of the Cu$_2$O core more intensive, due to the termination of amorphous CuO at D=7.

Figure 4. The observed (crosses) and Rietveld refined (solid lines) x-ray diffraction patterns of Cu$_2$O/CuO core-shell nanowires. The contribution of the intensity of the CuO shell cannot be seen in the x-ray patterns due to amorphous state.
The results of an early study (x-ray patterns) show that the prepared core-shell nanowires are crystalline. We further characterized the structure of sample using TEM microscopy. Figure 6 shows an example of the Cu$_2$O/CuO core-shell nanowires taken at D=4, which has a uniform coating of amorphous CuO (light contrast) surrounding a single-crystal Cu$_2$O core (dark contrast), forming core-shell Cu$_2$O-CuO nanowires. The chain-like configuration of the Cu$_2$O nanoparticles intertwined with the nanowires can also be observed. The results are in good agreement with the NVT Monte Carlo (MC) method [Phillies, 1974] results for the intermediate state of pearl necklace-like aggregates. In the MC simulation gives the formation of nanowires involves a process where Au nanoparticles could self-assemble into chain-like intermediate states then recrystallize into one-dimensional nanowire. The dipole-dipole-interaction in the Cu$_2$O nanoparticles is strong and long-range, leading to the formation of the pearl necklace-like nanostructures. A significant surface CuO layer (a few nms in thickness) was observed, indicating the existence of an amorphous CuO shell. In order to determine the amorphous CuO and the surface characteristics of the core-shell nanowires, we have utilized XANES technique to examine the existence of surface CuO thickness, simulating through an intensity ratio of Cu$_2$O-core and CuO-shell by using a proposed core-shell nanowire model.

For a cylindrically multilayered structure without consider the effect of diameter distribution. An electron being photoionized into the surface CuO has a probability of escaping through the surface without suffering any inelastic processes. Therefore, it can be detected as a photoelectron. In generally, the probability is conveniently expressed in terms of the mean free path for surface layer $\lambda_{CuO}$ and core $\lambda_{Cu2O}$, respectively. The intensity of ionized electron is proportional to $I_p \exp(-f/\lambda)$, where $f$ is the distance between the surface and the point of origin of the photoelectron, $I_p$ is the normalization constant depends on the nano-
crystals. Thus, integrating the portion of contribution intensity over the cylindrical volume, then we can easily obtain the total intensity from each of the two regions of the nanocrystals. The total intensity from each region in terms of cylindrical polar coordinates can be expressed as [Nanda et al., 1999]:

\[ I = I_0 \int_{\phi_1}^{\phi_2} \int_{\rho_i}^{\rho_f} \exp \left[ -\frac{f(r, \phi, z)}{\lambda} \right] r \, dr \, d\phi \, dz, \]

(3)

where \( L \) is the length of the nanowire, \( \lambda \) is the mean free path of the photoionized electron, \( R_1 \) is the radius of the core, \( R_2 \) is the radius including the surface layer. The distance between the surface and the point of origin of the photoelectron then can be schematically plotted in Fig. 7 and defined as:

\[ f(r, \phi, z) = \left[ \sqrt{R^2 - r^2 \cos^2 \phi - r \sin \phi} \right]^2 + z^2 \]

(4)

The mean free paths of \( \lambda_{\text{CuO}} \) and \( \lambda_{\text{Cu}_2\text{O}} \) used in this study are obtained from previous reports [36]. The mean free paths of \( \lambda_{\text{CuO}} \) and \( \lambda_{\text{Cu}_2\text{O}} \) used in the simulation are defined as

\[ \lambda_{\text{CuO}} = \frac{0.0062 E_p (\text{Cu}^{2+})}{\log(0.0501 E_p (\text{Cu}^{2+}))} \quad \text{and} \quad \lambda_{\text{Cu}_2\text{O}} = \frac{0.00767 E_p (\text{Cu}^+)}{\log(0.0501 E_p (\text{Cu}^+))} \]

\( \text{nm} \)

(5)
In order to clarify the contribution from Cu$_2$O- or CuO- intensity, we have defined a theoretical integrated intensity ratio $\gamma$ taken as:

$$\gamma = \frac{I_{\text{Cu}_2\text{O}}}{I_{\text{CuO}}} = \frac{I_0 \int_{-\frac{L}{2}}^{\frac{L}{2}} \int_{-\frac{R}{2}}^{\frac{R}{2}} \int_{-\frac{R_z}{2}}^{\frac{R_z}{2}} \exp \left[ -\frac{f(r,\phi,z)}{\lambda_{\text{Cu}_2\text{O}}} \right] r dr d\phi dz}{I_0 \int_{-\frac{L}{2}}^{\frac{L}{2}} \int_{-\frac{R}{2}}^{\frac{R}{2}} \int_{-\frac{R_z}{2}}^{\frac{R_z}{2}} \exp \left[ -\frac{f(r,\phi,z)}{\lambda_{\text{CuO}}} \right] r dr d\phi dz} \quad (6)$$

The above ratio cannot be evaluated analytically, and we can compute numerically by varying these parameters of $R_1$ and $R_2$, respectively, to match the experimental integrated intensity ratio of $\gamma = I_{\text{Cu}_2\text{O}}/I_{\text{CuO}}$. The electronic geometric structure around Cu in the as-synthesized material was characterized with X-ray absorption near edges (XANES) measurements. XANES spectroscopy of Cu L$_{2,3}$-edge was performed using the 6-m HSGM beam-line (BL20A1) of the National Synchrotron Radiation Research Center in Hsinchu, Taiwan. The recorded spectra were corrected for the energy dependent incident photon intensity as well as for self-absorption effects and normalized to the tabulated standard absorption cross sections in the energy range of 900-1020 eV for the Cu L-edge. The radiation was monochromatized using a 6m SGM monochromator and the photon energy was calibrated by measuring X-ray absorption spectrum of Cu metal foil by using the Cu L$_3$ white line. Figure 8 shows XANES spectra of as-synthesized material and copper based references such as Cu$_2$O (red curve), CuO (green curve) bulk. The main peak of Cu 2P$_{3/2}$ at 932.3 eV reveals the presence of Cu$_2$O phase. It is accompanied by a second peak at 935.1 eV related to the CuO phase, and can be regarded as characteristic of Cu$^+$ and Cu$^{2+}$ ($2p_{3/2} \rightarrow 3d$), respectively [Yin et al., 2005; Xu et al. 2007; Wen et al., 2005]. It is worth noting that the occurrence of a weak broad satellite feature on the higher energy (~ 943.5 eV) side of the Cu 2p main peak indicates the slight presence of CuO on the surface. The observed amount of CuO is very tiny due to the slightly oxidized surface of Cu2O nanowires. These results are well consistent with the XRD and TEM observations shown in Figs. 3 and 6. This result can be understood as due to the occurrence of amorphous CuO and crystalline Cu$_2$O on the surface and core, respectively. Based on the proposed core-shell model, we use the proposed model of a single core-shell nanowire with an inner crystalline Cu$_2$O core coated by a thin amorphous CuO surface layer to simulate the ratio of integrated intensity. These can be obtained from the data. The intensity ratio of the Cu$_2$O core and CuO shell is thus determined by integrating the peak intensity $I_{\text{Cu}_2\text{O}} / I_{\text{CuO}}$. Then we can tune the value of $R_1$ and $R_2$ in the model to fit the ratio of $I_{\text{Cu}_2\text{O}} / I_{\text{CuO}}$. All the parameters are allowed to vary simultaneously. Refining processes are carried out until the results meet the ratio of $I_{\text{Cu}_2\text{O}} / I_{\text{CuO}} = 3.302$ obtained from XANES. The refined parameters, as calculated from the model are listed in Table 1. From XANES analysis, we can conclude that the core-shell nanowires are mostly of Cu$_2$O phase. However, CuO phase in the as-grown sample could be explained either by the surface oxidation in liquid ethyl alcohol or by the core-shell-type of structure of Cu$_2$O nanowires with CuO as the capping layer [Sahoo et al., 2009; Yu et al., 2007].
Figure 7. Schematic models of core-shell nanowires based on the photoemission core-level analysis. (a) Top view of this model, where $R_1$ is the radius of core and $R_2$ is the radius including surface layer. (b) Side view of the proposed model, where the penetrated distance is $f(r, \varphi, z)$ and the $r$ integration is over suitable limits.

4. Conclusion

A new type of spontaneous organization method was successfully utilized to grow \( \text{Cu}_2\text{O}/\text{CuO} \) core/shell nanowires by immersing copper nanoparticles into liquid alcohol at room temperature. The microstructure of the nanowires during the nucleation and growth process from \( \text{CuO} \) nanoparticles into \( \text{Cu}_2\text{O}/\text{CuO} \) core-shell nanowires can be examined using time dependent in situ x-ray diffraction, SEM, and TEM. We show that the reactions of \( \text{Cu} \) nanoparticles oxide to form \( \text{Cu}_2\text{O}/\text{CuO} \) core-shell nanowires can occur at room temperature with unusually fast reaction rates. An intermediate state of pearl necklace-like aggregates formed by a chain-like configuration of \( \text{Cu}_2\text{O} \) nanoparticles was observed which then intertwined to form the nanowires. The results agreed with the prediction of NVT Monte Carlo simulation [Phillies, 1974]. A significant thin surface layer was observed on \( \text{Cu}_2\text{O} \) nanowires, indicating the existence of an amorphous \( \text{CuO} \) shell, as also confirmed by the x-ray absorption near-edge structure technique.
