1. Introduction

Biodiversity is a wide term that includes all the hierarchy of life in the Earth. However, this word refers to the whole biological diversity: ecosystem diversity, species diversity and genetic diversity. Those three levels of diversity are melt one in another. The basal level involves genetic diversity that includes variation within and among individuals that are grouped in populations. In the next level, populations may differentiate due to mutations, genetic drift and different environmental pressures into distinct species. Finally, ecosystems are characterized by different assemblages of species (Hunter, 1996).

The biological communities observed today were formed along millions of years, although most of those biomes have been already affected by human activity, including many severally endangered regions of the world (Primack & Rodrigues, 2001). Some human activities that affect natural environments are as deforestation, coast occupation, overhunting and introduction of exotic species. Thus, nowadays, the great challenge for conservation of natural systems is to conciliate human activities and conservation. The discipline of conservation biology emerge as answer to this crisis, with multidisciplinary approaches that aim to investigate the human impacts on natural populations, biological communities and ecosystems; to developed practice to prevent the environmental degradation and species extinction, restoration of ecosystems and reintroduction of populations, to establish sustainable relationship between human communities and ecosystems (Rozzi et al., 1998). However, all remaining ecosystems have been previously affected by multiple natural impacts such as climatic changes during the Pleistocene. Then, conservation biology also aims to discriminate between impacts due to natural events from those due to anthropogenic causes affecting current biodiversity distribution.

Biogeography, community ecology and population genetics attempt to describe how biological diversity is spatially distributed at different geographic scales (Miller et al.

2010, Diniz-Filho et al. 2008). Into this context, the molecular biology provides the tools to further investigate phylogenetic relationships among organisms, which can be associated with geographical distribution. With technological advances, the molecular markers have been increasingly applied to access genetic partitions among geographically isolated populations. The relationship between gene genealogies and geography can be used to estimate historical processes that can be responsible for contemporary geographic distributions of individuals and species. This new discipline, the phylogeography, is enabling us to understand processes of diversification, and to reconstruct the historical relationships considering explicit biogeographic hypotheses (Smith & Patton 1993, Patton et al. 1994).

One of the oldest and likely most recognized biodiversity patterns is the latitudinal gradient of species richness (Rosenzweig 1995, Miller et al. 2010). The marked difference in biodiversity richness from regions of high and low latitudes is well documented across distinct taxonomic levels and constitutes a widely recognized biogeographical pattern (D'Horta et al. 2011, Willig et al. 2003). The description of geologic, biogeographic and genetic patterns along tropical ecosystems helps us to better understand the differential effects of evolutionary history of low latitudes in the biodiversity dynamics. In this context, the objective of this chapter was to review the hypotheses of diversification proposed to explain the current biodiversity distribution observed in Brazilian Atlantic Forest. We present here each hypothesis and the different studies supporting or rejecting them.

The Atlantic forest is distributed along eastern and southwestern Brazil, eastern Paraguay, and north-eastern Argentina (Gusmão Câmara, 2003). The Brazilian Atlantic Rain Forest originally presented an area of 1.1 million km² and covered a large extension of the coast. Given this large geographic extent, the Atlantic Forest is floristically diverse with severe regional forms of rainforest (ombrophilous) and semi-deciduous forest, depending on rainfall regimes (Oliveira-Filho & Fontes, 2000) (Figure 1). Nowadays, this biome is considered one of the most important conservation hotspots of the World, because of its high levels of endemism and degradation. For example, although near 200 endemic species of birds are reported there, only 5% of its original area remain (Myers et al., 2000). The last estimates account for approximately 20.000 vascular plant species and over 2.300 vertebrate species, half of them being endemic and about 150 with threatened status (Conservation International do Brasil *et al.*, 2000). Furthermore, most of the remaining forested areas are located in regions of steep topography, where agriculture and cattle ranching are not economically viable.

The Atlantic forest biota is probably the result of a complex evolutionary history; however, the processes that shaped it are not well known (Mustrangi & Patton, 1997; Costa *et al.*, 2000; Smith & Patton, 2001; Pellegrino *et al.*, 2005). The knowledge of these evolutionary processes is extremely important for conservation purposes (Moritz, 2002). Among the hypothesis for diversification in Atlantic Forest, the models of Pleistocene refuges, gradient hypothesis; rivers as barriers and orogeny changes have been well discussed. All hypotheses are based in some provisional reductions gene flow among populations, which promoted divergence in allopatry, when the populations became different because they were somehow geographically isolated.

In the following section we discuss each hypothesis.

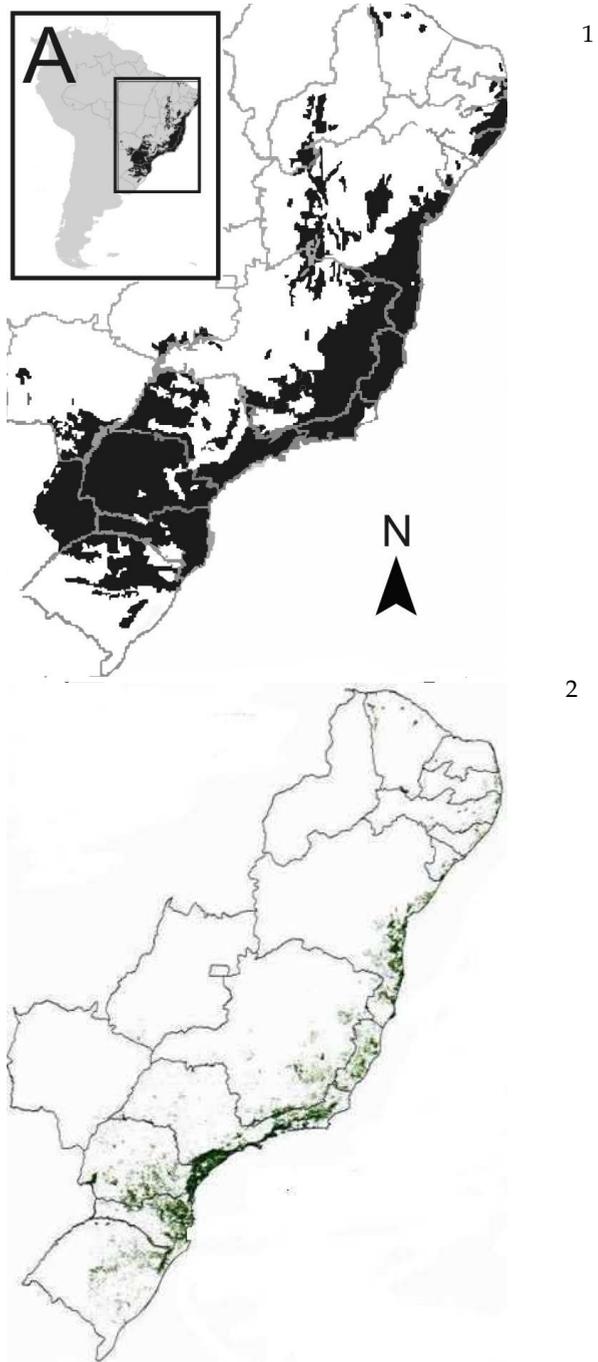

Fig. 1. Original (1) and remain (2) spatial distribution of Brazilian Atlantic Forest .

2. Pleistocene refuges

The refuges theory is one of the most discussed models of diversification to explain the origin of the diversity of the Atlantic forest. In the Neotropics, the refuge theory was originally proposed to explain speciation during the Pleistocene mainly in the Amazon basin (Haffer, 1969; Vanzolini & Williams, 1970; Brown & Ab'Saber, 1979; Haffer & Prance, 2001). This theory proposes that during the glaciations the rainforests were reduced to refuges isolated by open areas, and that organisms isolated in these refuges could have diverged and originated new lineages. Then, in the next interglacial period, the forest expanded and the new clades would be in secondary contact. Brown and Ab'Saber (1979) proposed that open areas dominated the Atlantic forest's landscape during the maximum of Late Pleistocene glaciations, suggesting that the refuge theory can be important to understand the biological diversification of the biome. Taxa may have evolved in allopatry within refuges (rainforest relicts) due to evolutionary factors as genetic drift and divergent selection.

The refuges hypothesis predicts to find evidence of high species endemism and high genetic diversity in the areas with high stability or forest in the past (refugial zones) and, in contrast, lower diversity, lower endemism and molecular signatures of recent range expansion within species in unstable, recently recolonized regions (non-refugial areas) (Carnaval & Moritz 2008). Moritz et al. (2000) and Thomé et al. (2010) affirmed the refuges hypothesis still need to consider additional predictions: the presence of sister taxa in adjacent refugia, secondary contact zones between refugia and range expansion out of refugia area refuges areas.

Carnaval & Moritz (2008) used climatic and forest distribution models and predicted the existence of a large and stable forest refuge in the state of Bahia, in the northeast of Brazil, and smaller refuges located along the Brazilian coast, one area north of the Paraíba river, called Pernambuco refuge, and possibly many small patches south of the Doce River and severe forest contraction south of the São Paulo state (Figure 2). Thomé et al. (2010) also used paleoclimatic modeling to suggest five stable areas in Atlantic Forest to *Rhinella crucifer* (toad) (1) the coastal region of north eastern Brazil, ranging from Alagoas to Rio Grande do Norte, called Pernambuco region; 2) southeastern Brazil, ranging from Rio de Janeiro to Espírito Santo and eastern Minas Gerais; 3) coastal south-southeastern Brazil, ranging from north Santa Catarina to São Paulo (called Serra do Mar); 4) the interior of the Paraná state; and 5) central-north Rio Grande do Sul state and western Santa Catarina state. Thomé et al. (2010) and Carnaval & Moritz (2008) showed many concordant refuges, with a difference that Thomé et al. (2010) found more areas in south Brazil due likely to specific habitat conditions of *Rhinella crucifer* (Figure 2).

Many studies have also found the phylogeographic patterns along Atlantic Forest that are compatible with predictions of the refuge hypothesis. For example, D'Horta et al. (2011) observed that in the study of intrapopulation genetic variation of *Sclerurus scansor* (Rufous-breasted Leaf-tosser) is compatible with that proposed by refuges hypothesis. They found three groups well defined, one in north of Atlantic Forest (Ceará state), another in central (Bahia, Minas Gerais and north São Paulo State), and a last one the south (Southern São Paulo, Santa Catarina and Rio Grande do Sul State). The estimate of the divergence time between lineages point to events during the middle and late Pleistocene, a period for which there are extensive records documenting change in forest distribution associated with climatic cycles.

Cabanne et al. (2007) also demonstrated demographic changes in *Xyphorhynchus fuscus* (Lesser Woodcreeper) consistent with responses to Pleistocene forest contractions and subsequent advances into southern areas of the Atlantic biome in responses to late Quaternary climate change. The same pattern was found to *Conopophoga lineata* (Rufous Gnateater), which showed data consistent with differentiation in the Pleistocene period (Pessoa, 2008). In some cases, those lineages showed also a secondary contact due to recent expansion in the Holocene period, as it has been found between south Minas Gerais State and North São Paulo, for *Xyphorhynchus fuscus* (Lesser Woodcreeper)(Cabanne et al. 2007) and *Conopophoga lineata* (Rufous Gnateater) (Pessoa 2008) and *Sclerurus scansor* (Rufous-breasted Leaf-tosser) (D'Horta et al. 2011).

Martins et al. (2009) also found two phylogroups in *Desmodus rotundus* (common vampire bat) whose estimate divergence times fall within the Pleistocene epoch, suggesting this bat is susceptible to forest fragmentation into refuges. Pavan et al. (2010) studied other species of bat *Carollia perspicillata* (Short-tailed fruit bat), also found two clades whose dating corroborated the vicariant event occurring in the Pleistocene, following by recent population expansion. Moraes-Barros et al. (2006) inferred two main phylogeographic groups exist in the Atlantic forest for *Bradipus torquatus* and *Bradipus variegatus* (Sloth) representing north (Southeastern region of Bahia State north of Minas Gerais) and south (Espírito Santo and São Paulo)

The difference between clades north and south observed in several Atlantic Forest species, led to the discussion about the influence of latitudinal gradient. The Atlantic Forest covers the 2° to 30° S alongside the Brazilian coast, consequently presents significant differences in temperature and humidity, which in the past could have affected the number of refuges. The influence of the latitudinal gradient affecting the biodiversity is one of the oldest and most recognized patterns associated to species richness (Rosenzweig 1995). Because of the strong historical effect that Pleistocene era glaciers had on the biogeography of higher latitudes, it is perhaps not surprising that post-glacial expansion is usually considered primarily responsible for the observed genetic diversity patterns (Hewitt 1996, Miller et al. 2010). Vellend (2003) and Vellend and Geber (2005) noted that the same biogeographic conditions favorable to high species richness within community (i.e. high immigration rates and low extinction rates) should promote high genetic diversity within the species comprising that community (Miller et al. 2010). Many studies focused on temperate zone organisms have suggested that latitudinal patterns of within population genetic diversity are most likely due to a history of post-glacial poleward habitat expansion (Miller et al. 2010). The latitudinal biodiversity gradient may reflect the distinct influence of Pleistocene glacial and interglacial cycles in the geographic landscape (Hewitt 2004). Because of the strong historical effect that Pleistocene glaciers had on the biogeography of higher latitudes, it is perhaps not surprising that post-glacial expansion is usually considered primarily responsible for the observed genetic diversity patterns (Hewitt 1996, Miller et al. 2010). In accordance with D'Horta et al. (2011) the latitudinal gradient hypothesis makes some explicit predictions: 1) populations from higher latitudes experienced more pronounced change in their effective population sizes and therefore exhibit signatures of recent demographic expansion and a lower genetic structure; 2) populations from lower latitudes experienced smaller or no changes in effective sizes, thus presenting higher diversity and genetic structure. Carnaval et al. (2009) observed that amphibians from Atlantic Forest showed higher levels of genetic diversity and structure of population in lower than higher latitudes. Some studies of mammals, birds and reptiles have found latitudinal

differentiation along the Brazilian Atlantic Forest, and showed an expansion signal in lower latitudes (Pavan *et al.* 2011, Grazziotini *et al.* 2006, Martins *et al.* 2009). However, these studies did not report higher genetic diversity in northern population (lower latitudes), as it would be expected under gradient hypothesis.

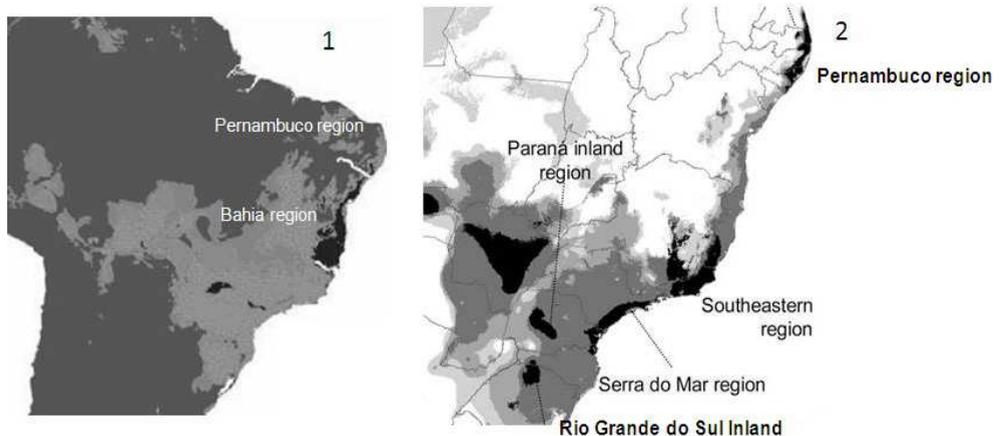

Fig. 2. Summary maps of historically stable areas for the Atlantic forest definitions, obtained by (1) Carnaval and Moritz (2008) summing across BIOCLIM and MAXENT output grids for forest absence/presence under current and (2) Thomé *et al.* (2010) models of habitat distribution for current time, last interglacial period (LIG), last glacial maximum period (LGM).

3. Neotectonic hypothesis

The Atlantic margin of the South American plate is tectonically passive (see Thomé *et al.* 2010), although little changes occur, causing faults and fractures and consequently affect dated sedimentary deposits, regional uplifts consequently remodeling the landscape (Ricommini & Assumpção 1999). In the Brazilian Atlantic Forest many changes may have been caused by the uplift of the coastal Brazilian mountains (Serra do Mar). Those events possibly interrupted precipitation in southeastern Brazil by the early Pliocene at about 5.6 Ma and therefore altered the distribution of humid and dry habitats. This period coincides with the transition from tropical humid to semiarid or arid conditions described by some authors (Simpson 1979; Vasconcelos *et al.* 1992). This orogenic process deeply changed the geomorphologic and climatic conditions of south and southeast areas of Brazil, and consequently fragmented Brazilian Atlantic Forest with drier areas (Grazziotini *et al.* 2006). The palynological record of the Quaternary showed that between 33,000 and 25,000 years ago, the central Brazilian region was moister than today and was covered by rainforest (Ledru 1993), and during the last glaciation (18,000-12,000 years ago) the present day corridor of xeric vegetation was covered by extensive woodland (Prado & Gibbs 1993, Costa *et al.* 2003). It is believed that during drier periods, forest formations

were more likely to occur in mountain areas, because of the higher pluviometric level resulting from orographic effect. Such phenomenon is currently observed in north-eastern region of Brazil, where the occurrence of humid forests is strictly associated with areas of mountain ridges (D'Horta et al. 2011).

Mountain chains often delimit Atlantic Forest distribution, but few studies have established geomorphological events as promoter of allopatric diversification in this biome (Thomé et al. 2010). Neotectonic activity has significantly remodeled the landscape of eastern Brazil during the Quaternary, confounding the signatures of isolation mechanisms along this Tertiary-Quaternary time scale. Thomé et al. (2010) found that the distinct phylogroups concordant with neotectonic barriers in Guapiara lineament and the Cubatão Shear zone in the São Paulo State, both including recent superficies ruptures (Ricommi and Assumpção, 1999). Although, the tectonic events in the region occupied by Brazilian Atlantic Forest are still poorly understood, they may be an alternative explanation to observed patterns.

4. Riverine barriers

The rivers can play an important role in biological diversification as they may act as primary or secondary barriers to gene flow and may have been important to model the current biota distribution. Siedchlang et al. (2010) suggest that the São Francisco River was an important barrier to *Calyptommatus* (lizards), allowing speciation on opposite margins of the river, being responsible to present distribution of *C. sinebrachiatus* and *C. leiolepis*, as well as that of *C. nicterus* and *C. leiolepis*, which occurred in adjacent banks on opposite margins. Thomé et al. (2010) observed that *Rhinella crucifer* group presents divergent lineages spatially concordant with Doce River systems and refute the refuges model to diversification this group. Also, Lacerda et al. (2007) presented genetic data that suggested a role of the Jequitinhonha river and Doce river for separating populations of passeriformes *Thamnophilus ambiguus* (Sooretama). Pellegrino et al. (2005) show also that the genetic structure of lizards of the *Gymnodactylus darwinii* complex coincides with the river system in the northern regions of the Brazilian Atlantic Forest and that major coastal rivers in this region may have played a key role in its diversification

On the other hand, D'Horta et al. (2011) suggested for *Sclerurus scansor* that tectonic activity associated with the Paraíba Valley can be congruent with the scenario that the river was important for the secondary contact of lineages of the south and central of Atlantic Forest, but not for the origin of these lineages due to phylogeography rupture, because the divergence time is much more recent (middle/late Pleistocene). This hypothesis of secondary contact among lineages is corroborated by Cabanne et al. (2007) and Pessoa (2008), who also suggested Paraíba do Sul Valley as contact region of divergent mitochondrial lineages from *Xyphorhynchus fuscus* and *Conopophoga lineata*. Furthermore, in both margins of the Paranapanema river were also found two phylogroups of *Bothrops jararaca* (Grazziotin et al. 2006).

In summary, the riverine systems seem important to differentiation between lineages and species, thus, are relevant to consider in the evolutionary processes related to the Atlantic Forest diversification, mainly the São Francisco, Jequitinhonha, Doce and Paranapanema (Fig 3).

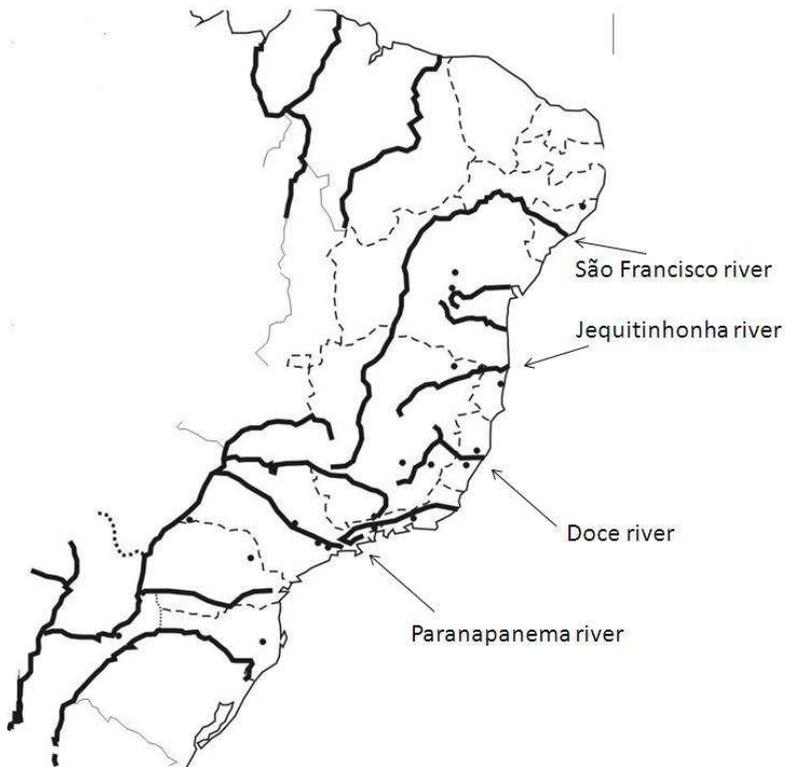

Fig. 3. Localization of mainly rivers that influence the distribution of species at Brazilian Atlantic Forest.

5. Gradient hypothesis

The Atlantic Forest is surrounded by dry forests and forested savannas (Cerrado). Because of the existence of a gradual transition from humid forest to those drier biomes, many organisms associated to humid forests are also found intermingled in the open biomes. Each region, the Atlantic forest and the neighboring regions, present different characteristics, and therefore it is expected to find differential selective regimes that could make organisms to diverge between regions. This hypothesis is known as the ecological gradient hypothesis. Also, there are different types of forests within the Atlantic Forest that could imply differential selective regimes. Even though this scenario is very plausible, few studies addressed the problem of divergence across ecological gradients in this biome. For example, Lara et al. (2005) mentions that the occurrence of species of tree rat *Phyllomys* and of spiny rat *Trinomys* is associated with vegetation types and with humidity gradients indicate that evolution across gradients may be important. Bird species show distributed in different zone of humidity and temperature across forest types in the Atlantic forest with, which could suggest an important role of environmental gradients in their evolution. So far only one study addressed the problem of evolution across gradients in the Atlantic forest. Cabanne et al (in press) studied whether the plumage color in *Dendrocolaptes platyrostris* was

related to change by drift in different populations historically isolated, or by selective change in different forest types. They found that the plumage variation was related to different forest types and not to historically isolated lineages, suggesting an important role of selection. *D. platyrostris* at the open vegetation corridor was lighter and less streaked than at the forest habitat, a morph which is suggested to be an adaptation of woodcreepers for habitats with high luminosity levels, as are forests at the open vegetation corridor (Marantz, 1997; Willis, 1992). On the other hand, rainforest individuals are darker and more streaked, what is considered to be an adaptation to live in low luminosity and very humid conditions (Marantz, 1997; Willis, 1992; Zink & Remsen, 1986).

Era	Period	Epoch	MYA	Event	Reference
CENOZOIC	Quaternary	Holocene	0.01		
		Pleistocene	1.8	Divergence lineage from <i>Sclerurus scansor</i> (Passeriformes)	D'Horta et al. 2011
				Divergence of lineages of <i>Xyphorhynchus fuscus</i> (Passeriformes)	Cabanne et al. 2007
				Divergence of lineages of <i>Conopophoga lineata</i> (Passeriformes)	Pessoa 2008
				Divergence of lineages from South the <i>Gymnodactylus darwinii</i> (lizards)	Pellegrino et al. 2005
				Divergence between lineages of <i>Carollia perspicillata</i> (bat)	Pavan et al. 2011
				Divergence of lineages of <i>Rhinella crucifer</i> center and north Atlantic Forest (toad)	Thomé et a. 2010
				Divergence of lineages of <i>Desmodus rotundus</i> (bat)	Martins et al. 2009
				Divergence of lineages of <i>Bradyptes torquatus</i> (Xenarthra)	Moraes-Barros et al. 2006
	Tertiary	Pliocene	5.3	Divergence of phylogroups of <i>Bothrops jararaca</i> (Serpentes)	Grazziotini et al. 2006.
				Divergence of lineages of North and south of <i>Rhinella crucifer</i> (toad)	Thomé et a. 2010
				Uplift Brazilian coast mountain	
		Miocene	23.0	Drainage of Parana river	Grazziotin et al. 2006
				Neogene sediments of the Barreiras Formation Doce River	
				Divergence of lineages North and South <i>Gymnodactylus darwinii</i> (Lizards)	Pellegrino et al. 2005

Table 1. The geological time scale and the resume of principal studies of Phylogeography in Atlantic Forest

The open vegetation corridor and its network of gallery forests and dry forests are contiguous with the Atlantic and Amazon forests. The results of Cabanne et al. (in press) supported the idea that the two plumages types of *D. platyrostris* may have evolved by divergent selection regimes between habitats. There are several other species that occur in both habitats and might present a similar evolutionary story. Puerto et al. (2001) found one clinal morphological variation to *Bothrops atrox* group, although did not show association with genetic variation, which revealed two clades concordant with division North and South of Forest Atlantic.

6. Conclusions

In conclusion, the separation of the northern and southern phylogroups observed at Atlantic Forest endemic species is a pattern found for several taxa, however the discontinuities were observed in distinct zones of the Atlantic Forest. Some discrepancies can be explained by sampling bias, but others can be due to real differences in the dynamics of the species or the associated ecosystem. Anyway, distinct mechanisms have been invoked to explain the breaks, sometimes they were attributed differences are attributed to refuges hypothesis and another times to riverine barriers or tectonic activities. Silva et al. (in press) studied the panbiogeographic nodes in Atlantic Forest found six of the seven nodes found one node (Pernambuco) in North AF, two nodes (Bahia and Espírito Santo) are in Central AF, and three nodes (São Paulo, Paraná and Santa Catarina) correspond to South AF and concluded that the pattern of latitudinal subdivision of *taxa* distributions has originated at least since the Miocene and is more complex than previously thought. The endemism areas are concordant with the stability areas proposal for Atlantic Forest, the great part of studies show differentiation between lineages in Pleistocene Epoch (Table 1). Due to the complexity of the geomorphological and ecological features of the Atlantic Forest, and the intrinsic complexity of the ecophysiology of the Atlantic Forest organisms, it seems too simplistic to imagine that one single diversification mechanism can explain the origin of the current biogeographical patterns exhibit by Atlantic Forest species (D'Horta et al. 2011). A realist scrutiny of the Atlantic Forest diversity and past ecosystem dynamics should consider multiple mechanisms operating at different spatial and temporal scales (Thomé et al. 2010).

The elucidating the process that acted in Atlantic forest is essential to understand the biodiversity present in this biome, and to conservation of lineages and species. Understanding the speciation process, the effects of climate oscillations will be important to estimate the consequence of global warming in this ecosystem. Predictions of ecological niche modeling to Brazil has indicated a decline of 80% of current distribution for half of the birds of the family Pipridae in Amazon and Atlantic Florest (Anciães & Peterson, 2006). Niches paleoclimate modeling combined with molecular analysis has pointed to cases of recent population expansion from refuges or ecologically stable areas with high diversity and population structure in the Atlantic in response to environmental changes in the Quaternary Period: amphibians, lizards (Carnaval et al. 2009, Carnaval and Moritz 2008) and birds (Cabanne *et al.*, 2008). Thus, the importance of the characterization of the distribution of the genetic diversity of threatened and non-threatened species is important to future conservation plans and politics efforts.

7. Acknowledgement

This chapter aim to understand the principal evolutionary processes that are related to the diversification and maintenance of the Atlantic forest biodiversity.

The author thank to Fundação de Amparo a Pesquisa do Estado de São Paulo (FAPESP), Conselho Nacional de Pesquisa do Governo Brasileiro (CNPq), Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES), Fundação de Amparo a Pesquisa do Estado de Minas Gerais (FAPEMIG) for given funding to develop these studies.

Ecosystems Biodiversity

Edited by PhD. Oscar Grillo

ISBN 978-953-307-417-7

Hard cover, 464 pages

Publisher InTech

Published online 16, December, 2011

Published in print edition December, 2011

Ecosystems can be considered as dynamic and interactive clusters made up of plants, animals and micro-organism communities. Inevitably, mankind is an integral part of each ecosystem and as such enjoys all its provided benefits. Driven by the increasing necessity to preserve the ecosystem productivity, several ecological studies have been conducted in the last few years, highlighting the current state in which our planet is, and focusing on future perspectives. This book contains comprehensive overviews and original studies focused on hazard analysis and evaluation of ecological variables affecting species diversity, richness and distribution, in order to identify the best management strategies to face and solve the conservation problems.
