1. Introduction

Transient liquid-phase (TLP) bonding is a material joining process that depends on the formation of a liquid at the faying surfaces by an interlayer that melts at a temperature lower than that of the substrate [1, 2, 3, 4, 5].

The TLP bonding is distinguished from brazing processes by the isothermal solidification of this liquid. This is accomplished since the interlayer is rich in a melting point depressant (MPD). Upon heating through the eutectic temperature, the interlayer will either melt or react with the base metal to form a liquid. During the hold time above the melting temperature, the melting point depressant (solute) into the base metal (solvent). This resulting solid/liquid interfacial motion via epitaxial growth of the substrate is termed “isothermal solidification.” A homogeneous bond between the substrates is formed when the two solid/liquid interfaces meet at the joint centerline marking the end of the isothermal solidification stage.

TLP bonding provides an alternative to fusion welding and has been extensively studied for joining particle-reinforced Al-MMCs [1]. The advantage of using this process is that, reinforcing particles are incorporated into the bond region either by using a particle reinforced insert layer or by the melt-back due to a eutectic reaction between the interlayer and the aluminum alloy [6]. It has been shown in the scientific literature that melt-back can be controlled by using thin interlayer materials. It has also been suggested that heating rate, interlayer composition and thickness are most important in reducing melt-back during TLP bonding. These parameters also determine the width of the liquid phase, removal of surface oxide film and particulate redistribution in the bonded region [16, 7,5].

According to Bosco and Zok [8] there exists a critical interlayer thickness at which pore-free bonds are produced. The thickness of the interlayer must exceed that which is consumed

through solid-state diffusion; otherwise, no liquid is formed at the bonding temperature. This sets a minimal requirement for the interlayer thickness, which can be determined using equation 1:

$$h_c = h_\eta C_\eta \left(\frac{\rho_\eta}{\rho_i} \right)^2 \quad (1)$$

Where, $2h_\eta$ is the total thickness of the reaction layer formed at the interlayer/MMC interface when the eutectic temperature is reached, C_η is the mass fraction of Ni in the reaction layer. The mass densities of the reaction layer and the Ni interlayer are ρ_η and ρ_{Ni} respectively. On the other hand, Li et al. [5] suggested that a maximum thickness exists that minimizes particle segregation and maximises joint strength. The composition of the interlayer has also been shown by Eagar and McDonald [9] to be equally as important as the interlayer thickness. In the published literature, it has been shown that pure metal interlayers such as nickel [10, 11], silver [12,13] and copper [13, 15] can react with the metal surface by means of eutectic or peritectic reaction to displace surface oxides and regulates the bonding temperature. In joints made using these pure interlayers, the existing problems can be summarized as: parent metal dissolution particulate segregation [13, 14,15], void formation in particle segregated region [12] and low strength micro-bonds at particle-metal interfaces resulting from the poor wettability of molten interlayer on ceramic reinforcement [12,16]. Particle segregation has been shown by Stefanescu et al [17, 18] to be promoted by the slow movement of the solid-liquid interface during isothermal solidification. Li et al. [5] showed that during TLP bonding of Al-MMCs containing particulate reinforcements with diameters less than 30 μm , particle segregation to the interface occurred when a copper foil thickness between 5 and 15 μm was used. Earlier research used alloyed interlayers such as; Zn–Al, Cu–Al and Cu/Ni/Cu systems to decrease bonding temperature in air and to prevent particulate segregation [19]. While composite interlayers such as Al–Si–W mixed powder and Al–Si–Ti–SiC mixed powder were used to improve the densification of a thick reaction layer which formed at the joint. This layer was reinforced with a metallic phase and a ceramic phase [20].

Recent studies into joining Al-MMCs have focused on decreasing bonding temperature by using Sn-based interlayers reinforced with silicon carbide. The results show that joint strength of Al6061 + 25% (Al_2O_3)p improved by approximately 100% when compared to unreinforced Sn-based joints formed by ultrasonic assisted soldering [21]. Yan et al. [22] developed a SiC particle reinforced Zn-based filler which was used to join SiCp/A356 composite. The results indicated that with the use of ultrasonic vibration suitable particle distribution and reduced void formation were achieved. Cooke et al. [23, 24] used an electrodeposited Ni- Al_2O_3 nano-composite coatings to join Al-6061 MMC. The results showed that the use of Ni- Al_2O_3 nano-composite coatings can be used successfully to increase joint strength when compared to TLP bond produced using pure Ni-coating. The results also showed that coating thickness of 5 μm can be used to control particle segregation during TLP bonding of Al-6061 MMC

In order to study the kinetics of TLP bonding, techniques such as wavelength dispersive spectroscopy, energy dispersive spectroscopy and x-ray diffraction spectroscopy are normally used, since the compositional changes across the joint region is the mechanism by which the process progresses to completion. In previous studies EDS, WDS and XRD has been used extensive for studying materials due in part to the flexibility that the techniques afford. In most papers, a choice is made between the two processes depending on the information that is required. The difference between these processes are that, the energy-dispersive (ED) type records X-rays of all energies effectively simultaneously and produces an output in the form of a plot of intensity versus X-ray photon energy. The detector consists of one of several types of device producing output pulses proportional in height to the photon energy. Whereas the wavelength-dispersive (WD) type makes use of Bragg reflection by a crystal, and operates in 'serial' mode, the spectrometer being 'tuned' to only one wavelength at a time. Several crystals of different interplanar spacing are needed in order to cover the required wavelength range. Spectral resolution is better than for the ED type, but the latter is faster and more convenient to use. X-ray spectrometers attached to SEMs are usually of the ED type, though sometimes a single multi-crystal WD. This chapter examines the application of spectroscopic analyses such as EDS, WDS and XRD to the evaluation of nanostructure TLP bonds using Ni-Al₂O₃ nano-composite thin film as a filler material during TLP bonding of Al-6061MMC. The effects of process parameters on the mechanical and microstructural microstructural changes in the joint region will also be studied.

1.1. Spectroscopic analysis techniques

The characterization of materials using spectroscopic techniques such as energy dispersive spectroscopy or x-ray diffraction spectroscopy techniques is dependent on the generation of a beam of electrons which interacts with the sample to be analyzed. When electrons strike a anode with sufficient energy, X-rays are produced. This process is typically accomplished using a sealed x-ray tube, which consists of a metal target and a tungsten metal filament, which can be heated by passing a current through it resulting in the "boiling off" of electrons from the hot tungsten metal surface. These "hot" electrons are accelerated from the tungsten filament to the metal target by an applied voltage. The collision between these energetic electrons and electrons in the target atoms results in electron from target atoms being excited out of their core-level orbitals, placing the atom in a short-lived excited state. The atom returns to its ground state by having electrons from lower binding energy levels make transitions to the empty core levels. The difference in energy between these lower and higher binding energy levels is radiated in the form of X-rays. This process results in the production of characteristic X-rays. X-rays are generated when the primary beam ejects an inner shell electron thus exciting the atom. As an electron from the outer shell drops in to fill the vacancy and de-excite the atom it must give off energy. This energy is specific to each individual element in the periodic table and is also specific to what particular electron dropped in to fill the vacancy. The conversion between energy, frequency, and wavelength is the well-known de Broglie

relationship: $E = h\nu = hc/\lambda$, where ν is the frequency, h is Planck's constant (6.62×10^{-34} joule-second), c is the speed of light (2.998×10^8 m/sec), and λ is the wavelength of the radiation (in m). Based on this relationship, two distinct types of x-ray detector systems are used. These two types of detector systems are called Energy-Dispersive x-ray Spectrometry (EDS) and Wavelength-Dispersive x-ray Spectrometry (WDS).

EDS spectrometer are most frequently attached to electron column instruments such as SEM or (EPMA). As the name implies is a method of x-ray spectroscopy by which x-rays emitted from a sample are sorted out and analyzed based on the difference in their energy level. An EDS system consists of a source of high-radiation; a sample, a solid-state detector (usually from lithium-drifted silicon (Si(Li))); and a signal processing electronics. When the sample atoms are ionized by a high-energy radiation, they emit characteristic x-rays. X-rays that enter the Si(Li) detector are converted into signals (charge pulses) that can be processed by the electronics into an x-ray energy histogram. This x-ray spectrum consists of a series of peaks representative of the type and relative amount of each element in the sample. The number of counts in each peak can be further converted to elemental weight concentration either by comparison standards or standardless calculations. In general, three principal types of data can be generated using an EDS detector: (i) x-ray dot maps or images of the sample using elemental distribution as a contrast mechanism, (ii) line scan data or elemental concentration variation across a given region, and (iii) overall chemical composition, both qualitative and quantitatively.

As the name implies, WDS is a detection system by which x-rays emitted from the sample are sorted out and analyzed based on differing wavelength (λ) in the WDS, or crystal spectrometry. As in EDS or imaging mode, the beam rasters the sample generating x-rays of which a small portion enters the spectrometer. As the fluorescent x-rays strike the analyzing crystal, they will either pass through the crystal, be absorbed, be scattered, or be diffracted. Those which satisfy Bragg's Law; $n\lambda = 2d \sin\theta$.

(where n = an integer, d = the interplanar spacing of the crystal, θ = the angle of incidence, and λ = x-ray wavelength) will be diffracted and detected by a proportional counter. The signal from this detector is amplified, converted to standard pulse size in the single channel analyzer and counted with a scalar or displayed as rate vs time on rate meter. By varying the positioning crystal one changes the wavelength that will satisfy Bragg's Law. Therefore one can sequentially analyze different elements. By automating crystal movements one can dramatically speed up the analysis time. Typically the WDS analysis is used to gain the same type of information that the EDS is used for, qualitative and quantitative and quantitative information, line scan and dot maps for elemental distribution.

1.2. X-ray diffraction

X-ray diffraction (XRD) is another quantitative spectroscopic technique which reveals information about the crystal structure, chemical composition, and physical properties of materials and thin films. These techniques are based on observing the scattered intensity of an X-ray beam hitting a sample as a function of incident and scattered angle, polarization,

and wavelength or energy. Similar to the EDS and WDS techniques discussed above X-ray diffraction is dependent on Bragg equation, which describes the condition for diffraction to occur in terms of the wavelength of the x-radiation (λ), the interplanar ("d") spacings of the crystal, and the angle of incidence of the radiation with respect to the crystal planes (θ). As the spacing between atoms is on the same order as X-ray wavelengths crystals can diffract the radiation when the diffracted beams are in-phase.

When the incident beam satisfies the Bragg condition, a set of planes forms a cone of diffracted radiation at an angle q to the sample. Since the cone of X-rays intersects the flat photographic filmstrip in two arcs equally spaced from the direct X-ray beam, two curved lines will be recorded on the photographic film. The distance of the lines from the center can be used to determine the angle q , which can then be used to determine the interplanar "d" spacing. X-ray powder diffractometers record all reflections using a scintillation detector (in counts per second of X-rays). The pattern of diffracted X-rays is unique for a particular structure type and can be used as a "fingerprint" to identify the structure type. Different minerals have different structure types, thus X-ray diffraction is an ideal tool for identifying different minerals.

2. Electrodeposition of the nano-composite Ni/Al₂O₃ coating

Composite coatings can be produced by co-deposition of fine inert particles into a metal matrix from an electrolytic or an electroless bath. This technique is getting interesting due to its ability to produce films with excellent mechanical properties such as wear resistance, corrosion resistance, and lubrication.

The preparation of a composite coating is done in two steps. First, an effective dispersion of fine inert particles is produced in the electrolyte. Next, the preparation of the composite coating is made by the manipulation of electrochemical conditions. An effective dispersion of inert particles in the electrolyte promotes the adsorption opportunity of inert particles on the cathode. It causes a higher volume content of inert particles in the composite coating. The mechanical properties of the composite coating are also promoted with the enhancement of the volume content of inert particles in the coating. In electrodeposited composites, the particles to be dispersed in the metal matrix are maintained in suspension in the bath by agitation and they become incorporated in the coating by a process known as electrophoresis.

A number of coating parameters were studied to determine the effect of each on the coating thickness: pH of the electrolyte, current density, electrolyte temperature, agitation frequency and deposition time [33]. Samples were coated for time intervals of 2, 4, 6, 8, 10, 15, 20 and 30 minutes. After electrodeposition, coating thickness was determined using a light microscope. Figure 1(b) shows the relationship between coating thickness and deposition time when; the current density was set to 1.0A/dm², pH 3.0, agitation frequency of 300 rpm and an electrolyte temperature of 50°C [25]. It was found that the coating thickness increased with increasing deposition time, in keeping with Faraday's law governing electrode reactions during electrolysis [26].

Figure 1. (a) TEM image of as-received nano-sized Al_2O_3 powder (b) Coating thickness as a function of electrodeposition time at 1.0 A/dm^2 and 50°C [33].

In this study, Al -6061/ Al_2O_3 p samples of dimensions $10 \times 10 \times 5 \text{ mm}$ were prepared to 800 grit abrasive paper and polished to $1 \mu\text{m}$ diamond suspension after which they were cleaned in an acetone bath. Acid pickling took place in a solution of 15 wt.% HNO_3 and 2 wt.% HF at 50°C for 2 minutes and then rinsed in distilled water. The plating solution was prepared by dissolving: 250 g/L $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$, 45 g/L $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, 35 g/L H_3BO_3 and 1 g/L Saccharin in distilled water. The Ni- Al_2O_3 composite coating was produced by adding 50g/L of ceramic particles to a separately to the nickel bath. The particles were thoroughly mixed into the solution for two hours and kept in suspension in the bath with a magnetic stirrer rotating at 300 rpm. The coating solution was maintained at a temperature of 50°C and pH of 3.0 [33]. The thickness of Ni- Al_2O_3 p coatings were controlled by the current density and plating time. The actual amount of Ni- Al_2O_3 p electroplated onto a surface was determined by the weight gain after the plating process. The coating thickness was calculated by using the equations 2 and 3:

$$\rho_C = \frac{\text{mass of coating}}{\text{Area} \times \text{thickness}} = \frac{m}{A \times t} \quad (2)$$

The density of the composite coating (ρ_C) can be calculated by using Equation 3 (rule of mixtures) where x_v is the volume fraction of alumina particles in the Ni- Al_2O_3 coating.

$$\rho_C = \rho_{\text{Al}_2\text{O}_3} x_v + \rho_{\text{Ni}} (1 - x_v) \quad (3)$$

2.1. Spectroscopic analysis of the film structure and composition

Wavelength dispersive spectroscopic (WDS) and X-ray diffraction (XRD) spectroscopic analyses of the coatings deposited were used to evaluate the distribution of the dispersion particles. Figure 2 shows an SEM micrographs of the coating produced by the co-electrodeposition of Ni + 18vol% (nano- Al_2O_3)p. Examination of the coatings using a light

microscope revealed the absence of surface defects and interfacial void, however Al_2O_3 particle clusters were present in the coating. This was attributed to particle clustering in the powder prior to the coating process as indicated by the TEM image of the as-received Al_2O_3 powder shown in Figure 1(a). The volume fraction of Al_2O_3 present in the coating was studied by digital x-ray mapping and these results are shown in Figure 3. From Figure 3b and 3c, the areas which contains a high concentration of Al_2O_3 are easily identify and corresponds to Al and O which would confirm the compound to be Al_2O_3 since the base coating is Ni.

Figure 2. (a) Surface of the Ni- Al_2O_3 coating and (b) Cross-section of the Ni- Al_2O_3 coating produced by electrodeposition [33].

3. Fundamentals of transient liquid phase bonding

TLP bonding requires that the base metal surfaces are brought into intimate contact with a thin interlayer placed between the bonding surfaces. The interlayer can be added in the form

of a thin foil, powder or coating [27, 28] which is tailored to melt by eutectic or peritectic reaction with the base metal. The liquid filler metal wets the base metal surface and is then drawn into the joint by capillary action until the volume between components to be joined is completely filled.

The driving force of TLP bonding is diffusion. A process which can be described by Fick's first and second laws. The first law describes diffusion under steady-state conditions and is given by equation 4:

$$J = -D \frac{\partial C}{\partial x} \quad (4)$$

Fick's second law describes a non-steady state diffusion in which the concentration gradient changes with time and can be expressed as shown in equation 5:

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} \quad (5)$$

Equation 6 shows a general solution for Equation-5 using separation of variables is [29]:

$$C(x, t) = \frac{1}{2\sqrt{D\pi t}} \int_{-\infty}^{+\infty} f(\xi) e^{\left(\frac{\xi-x}{\sqrt{4Dt}}\right)^2} d\xi \quad (6)$$

Where the error function solution for equation 6 is shown in equation 7:

$$C(x, t) = \frac{C_0}{2} \left[\operatorname{erf} \left(\frac{x-x_1}{\sqrt{4Dt}} \right) - \operatorname{erf} \left(\frac{x-x_2}{\sqrt{4Dt}} \right) \right] \quad (7)$$

If the following boundary conditions are applied to Equation-7, the concentration as a function of time can be calculated using Equation-8:

$$C(x, 0) = \begin{cases} C_0 & (x > 0) \\ 0 & (0 < x) \end{cases} \quad \text{and} \quad C(x, 0) = \begin{cases} C_0 & x = +\infty \\ 0 & x = -\infty \end{cases} \quad (8)$$

$$C(x, t) = C_0 \left(1 - \operatorname{erf} \left(\frac{x}{\sqrt{4Dt}} \right) + \operatorname{erf} \left(\frac{kx}{\sqrt{4Dt}} \right) \right)$$

TLP bonding can be conducted by one of two distinct methods. Method-I employs a pure interlayer which forms a liquid through eutectic reaction with the base metal and Method-II employs an interlayer with a liquidus temperature near the bonding temperature [2]. Method-II is most commonly used as it reduces the overall process time by decreasing the volume of solute to be diffused from the interface before the liquid is formed. On the other hand, method-I can be considered to be more effective in TLP bonding as the eutectic reaction is able to displace surface oxides during bonding. TLP bonding process was first divided into five discrete stages by Duvall et al. [30]. These stages were: heating, melting,

dissolution of the base-metal, isothermal solidification and homogenization of the excess solute at the bond-line. Zhou later condensed the TLP process to three stages: base-metal dissolution, isothermal solidification and homogenization [7]. In later work by MacDonald and Eager [9] the second and third stage described by Duvall were combined to give four stages; heating, melting and parent metal dissolution, isothermal solidification and homogenization. Zhou [7] reclassified his earlier work to include a heating stage. The second stage was also expanded to be dissolution and widening.

4. Effect of bonding variables on microstructural evolution

This section investigates the effects of bonding variables on the chemical and microstructural homogeneity across the joint region. Factors affecting TLP bonding are; bonding temperature, bonding time, contact pressure and interlayer thickness and composition. Contact pressure can also affect the strength of the bond produced and this has been reported extensive in the scientific literature. However in this work, when bonding pressure increased beyond 0.1 MPa the result is rapid creep failure during the bonding process. Therefore the bonding pressure was held constant at 0.01MPa. The effects of these parameters were evaluated using WDS and XRD to study the change in chemical composition across the joint region as a function of bonding variable.

4.1. Effect of bonding time on joint properties

Wavelength dispersive spectroscopic analyses of joints bonded at 600°C using a 5 μm thick Ni-Al₂O₃ coating as the interlayer as a function of bonding time as shown in Table 1. For joints bonded for 1 minute a large concentration of Ni remained at the interface after bonding. However, when the bonding time was increased to 30 minutes resulted in the elimination of the interface and an increase in the grain size within the joint. This disrupts the band of segregated particles at the interface (see Figure 4) and chemically homogenized the joint zone.

Figure 4. Light micrographs of joint bonded with 5 μm thick Ni-Al₂O₃ coating for: (a) 1 min (b) 30 min [23].

The segregation of particles was accredited to the pushing of micro- Al_2O_3 particles by the solidifying liquid-solid interface. Stefanescu [18] showed that particle pushing can be assumed to be a steady-state condition under which the interface velocity can be assumed to be equal the rate of isothermal solidification. Li et al. [5] suggested that the segregation tendency is dependent on the relationship between the liquid film width produced at the bonding temperature, particle diameter and inter-particle spacing. When the liquid film width is large enough that sufficient particulate material is contained in the melt, particles will be pushed ahead of the solidifying liquid-solid interface resulting in particle segregation at the bond-line. However if the liquid film width is less than some critical value, segregation should not occur.

In the reported studies on transient liquid phase diffusion bonding of Al-MMCs it was shown that the width of the segregated zone at the joint center increased with increasing bonding time. The opposite of this relationship was seen when using the Ni- Al_2O_3 coating. As the bonding time increased, the width of the segregated region decrease. This can be attributed to the heterogeneous nucleation of grains within the joint zone during solidification and this lead to grain refining at the joint. A high resolution SEM micrograph shown in Figure 5 revealed the presence of a nano-sized alumina particle at the center of a grain. EDX spectra of the particle showed Al and O in high concentrations with traces of Mg [23, 24, 33]. Comparing Gibbs free energy of formation at the bonding temperature for MgO (-1195 kJ/mol) and Al_2O_3 (-985 kJ/mol) it is found that Al_2O_3 is unstable in the presence of Mg hence it is like that some of the nano-size Al_2O_3 will decomposed to form MgAl_2O_4 compound. WDS analysis across the joint zone as a function of bonding time indicated that the Ni volume at the joint center varied between 3.122 wt% after 1 minute and 0.37 wt% after 30 minutes bonding time (see Table 1).

Figure 5. (a) SEM image of nano-particle present in the center of a grain (b) EDS analysis of nano- Al_2O_3 particle [23]

Time (min)	Fe / wt%	Ni / wt%	Si / wt%	Mg / wt%	Cu / wt%	Al / wt%
1	0.399	3.122	0.633	0.379	0.586	93.635
5	0.677	0.849	0.863	1.047	0.71	79.375
10	0.049	0.071	0.211	0.676	0.162	98.598
30	0.028	0.037	0.091	0.458	0.087	99.153

Table 1. WDS analysis of joints made at 600°C as a function of bonding time

4.2. Effect of temperature on joint properties

Wavelength dispersive spectroscopic analyses of the joint as a function of bonding temperature indicated that the Ni concentration at the interface decreased from 4.65 wt% to 0.19 wt% as the bonding temperature is increased from 570 to 620°C (see Table 2). This was attributed to an increase in the diffusivity of Ni from the interface into the base metal as the temperature increased. A review of the scientific literature shows that the diffusivity of Ni increased from $D_{570}=4.69 \times 10^{-13} \text{ m}^2/\text{s}$ to $D_{620}=1.58 \times 10^{-12} \text{ m}^2/\text{s}$ when the bonding temperature was increased from 570 to 620°C [10, 31].

A study of the joint microstructure for a bond made at 570°C revealed the segregation of Al_2O_3 particles to the bond-line as shown in Figure 6(a). When the bonding temperature was increased to 590°C the width of the particle segregated zone within the joint decreased to approximately 150 μm as shown in Figure 6 (b). Further increase in bonding temperature to 600°C also resulted in a reduction of the width of the segregated zone. A similar result was obtained when the bonding temperature was increased to 620°C (see Figure 6d). This observation was consistent with earlier literature, which suggested that the use of thin interlayers during bonding can help to control the degree of particle segregation taking place within the joint [5]. The micrographs indicate that the width of the particle segregated zone decreases with increasing bonding temperature. This can be attributed to particle pushing by the primary α -phase during solidification as shown in section 4.1 [17, 18].

Figure 6. Light micrographs of joint region for bonding temperatures of (a) 570°C and (b) 590°C (c) 600°C and (d) 620°C.

Temperature	Mg/ wt%	Ni/ wt%	Si/ wt%	Fe/ wt%	Al/ wt%
570°C	2.53	4.65	0.72	0.35	91.75
590°C	1.73	1.69	0.52	0.28	95.78
600°C	1.52	0.35	0.41	0.21	97.51
620°C	0.94	0.19	0.21	0.19	98.47

Table 2. Wavelength dispersive spectroscopic analyses of joints made at 600°C for 10 minutes composition as a function of bonding temperature (wt %).

4.3. Effect interlayer thickness on joint properties

The effects of interlayer thickness on microstructural development across the joint region and subsequent effect on joint micro-hardness and shear strength were investigated. According to Bosco and Zok [8], there exists a critical interlayer thickness at which pore-free bonds are produced. This critical interlayer thickness should correspond to maximum joint strength. Therefore the objective in this section is to identify the critical interlayer thickness that maximizes joint strength. Joints made without the use of an interlayer resulted in the formation of a “planar interface” due to the presence of a layer of surface oxide, which prevents metal to metal contact (see Figure 7a). This was corroborated by studies on the solid-state diffusion bonding of Al-MMC [15]. The inability to achieve effective bonding in the solid-state highlights the need for low melting interlayers. When a 1 μm thick Ni-Al₂O₃ coating was used as the interlayer a thin joint zone was achieved (see Figure 7b). However a WDS analysis of this region indicated the presence of a higher concentration of Al₂O₃ when compared to bonds made using a pure nickel coating of the same thickness. This was attributed to the presence of nano-sized Al₂O₃ particles in the joint zone and the presence of residual surface oxide.

Figure 7. Microstructure of joints bonded at 600°C for 10 min using (a) no-interlayer used (b) 1 μm thick Ni-Al₂O₃ coating (c) 9 μm thick Ni-Al₂O₃ coating [32].

Figures 8 show that the width of the segregated zone increased with increasing coating thickness. At a coating thickness of 2 μm a more chemically homogeneous joint was created

however WDS analysis showed pockets of oxide with the following composition 65.56 wt% and 28.15 wt% were still present at the interface. When the coating thickness was increased to 4 μm , a 95 μm wide segregated zone was at the joint center and the concentration of nickel remaining at the interface after bonding increased from 0.47 wt% with 3 μm thick coating to 0.58wt% when a 4 μm thick coating (see Table 3). Further increase in coating thickness to 5 μm , resulted in the formation of a 110 μm wide segregated zone while the nickel increased to 0.97 wt%.

Interlayer thickness (μm)	Mg / wt%	Ni / wt%	Si / wt%	Fe / wt%	Al / wt%
1	0.46	0.37	0.53	0.22	98.42
2	0.83	0.49	0.62	0.19	97.87
3	0.98	0.47	0.67	0.21	97.67
4	0.97	0.58	0.72	0.27	97.46
5	0.84	0.97	0.53	0.18	97.48
7	0.86	0.88	0.71	0.38	97.17
9	1.05	1.01	0.69	0.24	97.01
11	1.13	1.45	0.65	0.52	96.25
13	0.99	1.63	0.67	0.97	95.74

Table 3. WDS analysis of joints made at 600°C for 10 minutes as a function of interlayer thickness

Figure 8. Width of the particle segregated zone formed at within the joint as a function of interlayer thickness for pure Ni coating and Ni–Al₂O₃ coating [32].

The increase in the width of the segregated zone was attributed to increased liquid formation with increasing coating thickness. As the width of the eutectic liquid increases more Al_2O_3 particles are immersed in the liquid phase. These particles are pushed by the solid/liquid interface during isothermal solidification [5].

The width of the particle segregated zone was significantly lower than that achieved when pure Ni-coatings are used as the interlayer. The difference in the width of the segregated zone between joint bonded using pure Ni coating and Ni- Al_2O_3 coating was attributed to the presence of nano-size Al_2O_3 particle in the joint center and a reduction in the concentration of Ni (81.6 wt%) present in the coating, when Ni- Al_2O_3 is used (see Figure 13b).

4.4. Effect of nano-sized particle on joint properties

The effect of nano-sized particles on the microstructural development across the joint region was studied using energy dispersive spectroscopy (EDS). Figure 9(a) shows the microstructure of a joint bonded using a 5 μm thick Ni coating dispersed with 50 nm Al_2O_3 particles. From the micrograph a 50 μm wide particle segregated zone was seen within the joint center. Also present at the center of the joint are dark clumps, which EDS analysis suggested are oxide particles (Figure 10 a and b). The presence of the oxide clusters observed, are likely Al_2O_3 particles which agglomerated during the deposition process. When the coating particle size was increased to 500 nm Al_2O_3 , a similar result was obtained (see Figure.9b). WDS analyses of the joints as a function of particle size indicated that the Ni concentration of 0.95 wt% and 0.79 wt% for samples bonded using 500 nm and 50 nm respectively. The lower concentration obtained when 50 nm particles are used suggest a faster diffusivity of Ni during the bonding process. This was attributed to greater surface contact between the uncoated Al-6061 sample and the Ni- Al_2O_3 coating surface. Analysis of the roughness using SEM indicated that the surface roughness increased from 0.1 μm for coatings containing 50 nm particles to 0.25 μm for coating containing 500 nm particles.

Figure 9. Microstructure of joints bonded at 600°C for 10 min using (a) 5 μm thick Ni-(50nm) Al_2O_3 (b) 5 μm thick Ni-(500nm) Al_2O_3 [32].

Figure 10. EDS analyses of joints bonded at 600°C for 10 min using (a) 5 μm thick Ni-(500 nm) Al₂O₃ (b) 5 μm thick Ni-(50 nm) Al₂O₃ [33]

The micrograph shown in Figure 9 a thin segregated zone was formed at the joint center in both cases. The hypothesis is that the difference in the width of the segregated zone obtained is dependent on the differences in particle size, surface roughness of the coating and the distribution of the nano-sized particles in the joint zone during bonding. The presence of nano-Al₂O₃ along the interface was confirmed by TEM analyses which indicated that the nano-particles are arranged along the grain boundary as shown in Figure 11 which would impart a pinning effect as described by Orowan [24].

Figure 11. (a) TEM image of the bonded joint when nano-sized Al₂O₃ particles are used in the interlayer and (b) TEM image of a nano-Al₂O₃ particle located at a grain boundary [33].

5. Effect of bonding variable on the mechanical properties of the joint

5.1. Effect of bonding time the joint shear strength

The shear strength of joints made as a function of bonding time is shown in Figure 12 (a). The graph show that the shear strength increased with increasing bonding time from 68

MPa at 1 minute to 137 MPa at 30 minutes. When a Ni-Al₂O₃ coating was used as the interlayer for a bonding time of 10 minutes, shear strength of 136 MPa was recorded. However when a pure Ni coating was used under that same bonding conditions, shear strength of 117 MPa was achieved [23]. The differences in joint shear strengths obtained were attributed to the presence of a nano-sized dispersion of Al₂O₃ particles within the joint and the precipitation of nickel aluminide phases within the joint region. Shen et al. [34] showed that the increase in yield strength of the nano-particle reinforced aluminum alloy is related to particulate–dislocation interaction by means of the Orowan bowing mechanism. Orowan theory suggests nano-sized particles act as barriers to dislocation motion. This mechanism leads to dislocation pile-up and an increase in the joint shear strength [35].

Figure 12. (a) Effect of bonding time on joint strength using 5µm thick Ni- Al₂O₃ coating at a bonding temperature of 600°C and (b) Effect of bonding temperature on joint shear strengths made using 5µm thick Ni-Al₂O₃ coatings for 10 minutes [23, 24].

The fractured surfaces of the shear tested joints were analyzed to identify the mechanism of joint failure. Figure 13(a) shows the fractured surface of a bond made for a bonding time of 1 minute. The fractograph shows an undulating surface containing shear plastic deformation with some cleavage facets indicating a mixed failure mode. The fracture appeared to have propagated through the bond-line. The result of the fractographic analyses suggests that the mechanism of failure transitioned from brittle to ductile as the bonding time increases. When the bonding time was increased to 10 minutes (see Figure 18b). The surface was characterized by an undulating appearance of plastic deformation indicative of ductile mode of failure. Additionally, fractured micro-Al₂O₃ particles were observed at the fractured surface, indicating a transgranular fracture through the bond-line.

XRD analyses of the fractured surfaces of bonds made at 1 and 10 minutes are shown in Figure 14. The results indicated the presence of peaks for phases such as AlFe_6Si ($2\theta=38^\circ$), Al_9FeNi and AlFeSi . The literature showed that these ternary compounds forms readily in Al-Mg-Si-Fe-Ni systems through various peritectic reactions [17]. In addition, binary crystal phases such as Al_3Ni , Ni_3Si ($2\theta=78^\circ$), Al_3Si and Al_2O_3 compounds were also identified.

Figure 14. XRD analysis of the fractured surface of a bond made with $5\ \mu\text{m}$ thick $\text{Ni-Al}_2\text{O}_3$ for (a) 1 minute and (b) 10 minutes

5.2. Effect of temperature on joint shear strength

Joint shear strengths measured as a function of bonding temperature were obtained using a single lap shear test. A comparison of the joint shear strengths of bonds made at 570, 590,

600 and 620°C is shown in Figure 12(b). The test result show that the shear strength increased with increasing bonding temperature from 45 MPa at 570°C to 138 MPa 600°C. This increase in joint strength was attributed to the presence of nano-sized ceramic particles and the precipitation of intermetallic phases within the joint region. The formation of these nickel aluminide phases increased with increasing bonding temperature. Specimens bonded at 620°C gave the highest bond strength of 136 MPa. The effect of the nano-particles and the precipitated intermetallics on the composite was discussed by Zhang and Chan [45] and results in Orowan strengthening as discussed in the previous sections.

In order to compare the effect of bonding temperature on joint failure mechanisms the fractured surfaces were examined using SEM. The results collected suggested that the ductility of the joint increased with increasing bonding temperature. For a bonding temperature of 570°C a mix failure mode was observed with both shear rupture dimples and cleavage planes (Figure 15a). An XRD analysis of the fractured surface indicated a high concentration of Al_2O_3 particles (see Figure 16a). This indicated that at this temperature the matrix-particle (M-P) interface was the weakest point for crack propagation giving the lowest joint strength of (53 MPa). Fracture propagation was observed through the bond-line. When the bonding temperature was increased to between 590°C and 620°C XRD analyses of the fracture indicated that the amount of intermetallic formed within the joint increased to include the binary compounds Al_3Si , Al_3Ni and Ni_3Si which suggested that failure propagated through the bond-line. Additionally, peaks of the ternary phases AlFeSi ($2\theta=37$ and 68°) and Al_3FeSi ($2\theta=78$ and 84°). The presence of these compounds confirms the formation of peritectic reactions during bonding. At 620°C the fractured surface was characterized by shear ruptured dimples indicating a ductile failure mode which occurred in the parent metal adjacent to the bond-line.

Figure 16. XRD spectrum of the fractured surface of a joint made using a 5 μm thick Ni- Al_2O_3 coatings at (a) 570°C and (b) 620°C.

5.3. Effect of coating thickness on shear strength measurements

Figure 17 (a) shows the variation in joint shear strength values as a function of coating thickness. The graph shows that the shear strength increased with increasing coating thickness from 53 MPa at 1 μm to 144 MPa at 11 μm . This increase in joint strength was attributed to three phenomena: the presence of nano-size Al_2O_3 particles in the joint center, the segregation of micro Al_2O_3 particle to the joint zone and the precipitation of intermetallic phases such as Al_3Si , Ni_3Si , Al_3Ni , and Al_3FeNi within the joint region. As discussed in the previous sections, for composites containing nano-sized particles, strengthening is often explained by the Orowan mechanism [36, 37]. Orowan bypassing theory shows that when smaller particle reinforcements are used the result is a more effective pinning of dislocation motion compared to when micro-particles are used. This mechanism leads to an increase in joint strength and hardness.

Figure 17. (a) Joint shear strengths as a function of particle size using 5 μm thick coatings (b) Shear strength profile plotted as a function of Ni- Al_2O_3 coating thickness.

When the coating thickness was increased beyond 11 μm , a decline in the strength of the joints was observed. At a coating thickness of 13 μm , a joint strength of 80 MPa was recorded. This reduction in joint strength was attributed to the formation of densely packed micro- Al_2O_3 particle-rich regions along the bond interface and also due to an increase in the volume of intermetallics compounds such as AlFe_3Si within the joint. The literature shows that the volume fraction of the micro- Al_2O_3 particles within the joint is inversely proportional to the joint ductility. Therefore, as the width of the particle segregated zone increased the ductility of the joint decreases. This leads to embrittlement of the joint region and causes a reduction in joint strength [38,39, 40, 41]. The findings published in the scientific literature supports the results collected in this study.

Fractured surfaces of the shear tested joints were analyzed to identify the mechanism of joint failure and the composition of the fractured surfaces. Figures 18 shows the micrographs of the typical fractured surfaces obtained for joints that were bonded using coating thickness ranging from 1 to 3 μm , respectively. Fractographic analyses revealed that the fractured surface contained cleavage planes, which propagated through the bond-line. In addition, Al_2O_3 particles were visible at the fractured surface. Examination of the fractured surfaces revealed characteristics of a brittle fracture which suggest that insufficient eutectic liquid is formed when using coating thickness between 1 and 3 μm . Composition analysis of the fractured surfaces using XRD indicated the presence of peaks for Al_2O_3 , Ni_3Si and $\text{Ni}_{17}\text{Al}_{3.9}\text{Si}_{5.1}\text{O}_{48}$ compounds.

When an interlayer thickness of 11 μm (see Figure 19a) was used, the fractured surface showed evidence of both shear plastic deformation and fractured micro- Al_2O_3 particles indicating a ductile transgranular fracture. Samples bonded at this condition had the highest shear strength. This indicated a critical combination of segregated micro- Al_2O_3 particles and nano- Al_2O_3 . Crack propagation occurred in the base metal adjacent to the bond-line. The results suggest that within coating thickness range of 5 to 11 μm , sufficient eutectic liquid is produced, which facilitate good particle to matrix bonding resulting increased joint strength. The XRD spectrum shown in Figure 19 (b) indicated the presence of Ni_3Si , MgAl_2O_4 and Al_2O_3 compound at the fractured surface. Increasing the coating thickness beyond 11 μm resulted in the gradual transition of the fracture mode from ductile to brittle. At a coating thickness of 13 μm thick Ni- Al_2O_3 coating (see Figure 20), the surface is characterized by dimples along the interparticle regions indicating a ductile failure through the particle-rich regions along the bond-line. XRD analyses of the fractured surfaces indicate the presence of peaks for Al_2O_3 , NiAl_2O_4 and AlFe_3Si compound at the fractured surface (see Figure 20b).

The results suggest that the ductility of the joint region increased with increasing coating thickness up to 9 μm . When the coating thickness was increased beyond 9 μm the joint region transitioned from ductile to brittle. These transitions were attributed to an increase in the volume of eutectic liquid that forms with increasing coating thickness leading to interparticle contact.

5.4. Effect of interlayer particle size shear strength measurements

Figure 17(b) show the joint shear strength graph as a function of interlayer particle size. The result indicated that joint shear strength increased with decreasing particle size from 138

MPa with 500 nm to 142 MPa with 50 nm. This increase in joint shear strength was attributed to better distribution of nano-sized particles within the interlayer when smaller particle sizes are used. In both cases higher shear strengths were obtained than when pure Ni coating is used (117 MPa) [23]. The results indicate that joint strength of up to 90% that of the base metal (BM) is achievable when using a 50 nm diameter nano-sized particle-reinforced interlayer. Tjong [42] showed that the nano-particle size has a strong effect on the yield strength. The author suggested that a particle size of 100 nm is a critical value for improving the yield strength of nano-composites. Below this critical value the yield strength increases significantly with decreasing particle size. Similar results were obtained by Gupta and coworkers [43, 44]. Zhang and Chen [45] showed that the Orowan stress plays a major role in strengthening the nano-composites.

Figure 21 shows the fractured surface for a bond made using a 5 μm Ni- 50 nm Al_2O_3 particle. The fractograph showed shear plastic deformation, indicative of ductile fracture with a crack propagating primarily through the bond-line and a section of the base metal adjacent to the bond-line. A similar result was obtained when a dispersed particle size of 50 nm were used in the coating. XRD analyses of the fractured surfaces indicated the presence of peaks for Al_2O_3 , NiAl_2O_4 and $\text{Al}_{11}\text{Ni}_9$ compound at the fractured surface.

6. Mechanism of joint formation

The mechanism of bond formation using composite Ni- Al_2O_3 coating is discussed in this section. The experimental results and the scientific literature show that the joint formation during transient liquid phase diffusion bonding is completed in five distinct stages: interfacial contact and solid-state diffusion, eutectic melting and base metal dissolution, and isothermal solidification. These stages will be discussed thoroughly with reference to the change in composition across the joint region. Mathematical models for predicting the parameter settings when nano-composite coatings are used in joining will also be presented. The sub-section of this topic are as follows:

6.1. Interfacial contact and Solid-state diffusion

The first stage of transient liquid phase bonding involved heating the sample to the bonding temperature. During this stage of bonding, two mechanisms are thought to occur simultaneously, firstly an increase in interfacial contact between the coating surface and the Al 6061 surface and secondly, solid-state diffusion along the coating/MMC contact interface. The initial contact area between the one side of the coating and the metal surfaces is only a small fraction of the theoretical area available, due to the presences of micro-asperities of the surface of both the metal sample and the coating. However, under the effects of heating and an external pressure an intimate contact can be establish at the bonding surfaces, as the micro-asperities suffer plastic deformation. As the temperature increases greater plastic flow is achieved at the interface and the percentage contact area increases. This increase in the contact area results in an increased diffusivity of the solute (Ni) into the base metal. During the heating stage Ni diffuses deep into the Al-MMCs resulting in the formation of complex intermetallic compounds.

Figure 22(a) shows an SEM micrograph of a joint bonded using a 15 μ m thick Ni-Al₂O₃ coating as the interlayer. The joint was made at a bonding temperature of 600°C for 1 minute and shows three distinct reaction layers at the interlayer/MMC interface. The nano- Al₂O₃ particles that were co-electrodeposited with Ni can are clearly shown in Figure 22.

The composition of the reaction layers was determined quantitatively by energy dispersive spectroscopy (EDS) analysis and is shown in Table 4. The formation of reaction layers (L₂ and L₃) shown in Figure 22, occurred as a result of the inter-diffusion of Ni and Al. EDS analysis showed that L₁ was composed of a Ni-Al layer dispersed with nano-sized Al₂O₃ particles after a bonding time of 1 minute (see Table 4). Reaction layer L₂ on the other hand appears to be a nickel-aluminide with compositions of 50.7 (at %) Ni and 46.70(at %) Al. The L₃ layer contains approximately 24.30 (at %) Ni and 77.0 (at %) Al, which is likely to be NiAl₃ intermetallic. This compound is believed to form due to the low solubility of Ni in Al. This has been reported to be approximately 2.9 at% [46]. The saturation of the aluminum interface through the inter-diffusion of Ni and Al leads to the precipitation of the nickel aluminide intermetallic NiAl₃.

The phase diagram of the Ni + Al system indicates the thermodynamic stability of the γ' -Ni₃Al phase when formed in the nickel concentration range of about (74 to 76) at.% [46]. Additionally, the phase diagram of the (Ni + Al) system proposed by Nash et al. [47] showed that for aluminum concentrations exceeding 40 mol%, there exist three coexistence fields: (Al + NiAl₃), (NiAl₃ + Ni₂Al₃) and the non-stoichiometric intermetallic β -NiAl, which is formed in the concentration range 43mol% to 59 mol% aluminum. Rog et al. [48] determined the Gibbs free energy of formation for various intermetallic compounds forming in the Ni + Al system. The results showed that within the temperature range of 570°C to 620°C (843K to 893K) the nickel aluminide compounds listed in Table 4 are formed.

Based on the scientific literature, the compound formed in the reaction layer L₃ is likely to be the NiAl₃. This compound also appears on the right side of Equation 9 and is believed to

form due to low solubility of Ni in Al which has been reported to be approximately 2.9 at% [46]. The saturation of the aluminum interface through the diffusion of Ni can lead to the precipitation of the nickel aluminide intermetallic NiAl₃. The composition of L₂ indicates that the compound is likely NiAl.

Phase	ΔG_f° (kJ.mol ⁻¹)
Ni + Al = NiAl	-133.0 +/- 1.0
Ni + NiAl ₃ = Ni ₂ Al ₃	-144.1 +/- 0.8
2Ni + 3Al = Ni ₂ Al ₃	-311.0 +/- 1.7
Ni + 3Al = NiAl ₃	-166.8 +/- 0.9

Table 4. The standard Gibbs free energy values for the chemical reactions with nickel aluminides at 870K [48]

Layers	Al / wt%	Ni / wt%	Si / wt%	Mg / wt%	Compound
L ₁	12.5	87.5	0	0	Ni + Al ₂ O ₃
L ₂	46.71	50.67	0.27	0	NiAl
L ₃	72.84	24.31	0	0.55	NiAl ₃
L ₄	72.84	24.31	0	0.55	NiAl ₃

Figure 22. (a) SEM micrograph of joint bonded with a 15 μm Ni-Al₂O₃ coating for 1 min.

6.2. Liquid formation and base-metal dissolution

Immediately following the heating stage, eutectic melting ensues. According to Dmitry et al [50] there are two possible reactions which are capable of producing a liquid at the joint interface within this temperature range (570°C-620°C). Upon reaching a temperature of 565°C, the L₂ compound reacts with L₄ (88.4%Al and 2.08 % Si) to form a eutectic liquid (E1) along the bond interface as predicted by Equation 9 [46]. The compound formed in L₂ is consumed in the eutectic reaction and diffuses into the base metal. When the joint region was heated to 577°C a second eutectic liquid formed within L₄ as predicted by Equation 10 [49]. The formation of a eutectic liquid layer at the bond interface leads to faster inter-diffusion between Al and the Ni interlayer and this results in a gradual change in the composition of the joint region.

Dmitry et al. [50] carried out thermodynamic calculations of (Al-Mg-Si-Fe-Ni) quinary systems formed in aluminum alloys. The results showed that in alloys containing Al-Mg-Si-Fe-Ni, numerous ternary and quaternary reactions can occur that has the potential of producing a liquid phase. Some of the phases that contribute to these reactions are shown in Table 6. The XRD analysis of the fractured surfaces shown in the previous also indicated that presence of AlFe₃Si. This phase is possibly a variant of the β-phase family listed in Table 6.

Phase	Designation	Composition (wt%)	Density (g/cm ³)
Al ₃ Ni	ε	42Ni	3.95
Mg ₂ Si	M	63.2Mg; 36.8Si	4.34
Al ₃ FeNi	T	4.5-14Fe; 18-28Ni	3.40
Al ₃ FeSi	β	25-30Fe, 12-15 Si	3.45
Al ₃ FeMg ₃ Si ₆	π	10.9Fe; 14.1Mg; 32.9Si	2.82

Table 6. Chemical composition and density of phases formed in Al-Mg-Si-Fe-Ni system [50]

6.3. Base metal dissolution

Base metal dissolution is also an important part of the second stage of bonding. Research work published [1,2] on the mechanisms of TLP bonding showed that dissolution of the interlayer and base metal occurs simultaneously at the bonding temperature. In this study, holding at a bonding temperature above 577°C resulted in increased diffusion of Ni into the base metal and causes the liquid phase to spread between the bonding surfaces due to the effects of pressure and capillary action. The application of pressure enhances spreading of the liquid phase between the bonding surfaces due to capillary action. This spreading increases the contact area and induces the diffusion of Ni and Al into the liquid phase. This

results in more eutectic liquid formation and an increase in the width of the liquid phase at the joint, due to dissolution of a section of the base metal. Further increase in the bonding time to 5 minutes, resulted in the diffusion of the Ni into the base metal and away from the joint interface leading to the formation of eutectic or peritectic liquid along the grain boundary as indicated in the EDS analysis of the eutectic microstructure shown in Figure 23.

Figure 23. (a) SEM micrograph of joint bonded using a 25 μm Ni foil for 5 min and (b) EDS analysis of the joint region.

According to published studies [20,1] on the stages of TLP bonding, it is expected that dissolution of the interlayer and base metal occurs simultaneously at the bonding temperature followed by spreading of the liquid phase between the bonding surfaces. This spreading increased the bonded area and enhanced the diffusion of Ni and Al into the liquid phase. This continuing diffusion resulted in more liquid formation and an increase in the width of liquid phase. The maximum liquid width attained when using the Ni- Al_2O_3 composite coating as the interlayer was found by Cooke et al [24] to be $W_{\max} = 20.6w_o$.

6.4. Isothermal solidification

In TLP bonding, prolonged hold time at the bonding temperature for 10 minutes allowed for the diffusion of Al into the eutectic liquid which caused the composition of the liquid phase to become aluminum rich, resulting in a change in the eutectic composition (see Table 6). The change in the joint composition initiates the isothermal solidification stage of TLP bonding as a function of bonding time since the temperature and interlayer thickness is constant. When the bonding time is increased to 10 minutes the interface is eliminated and the grain size within the joint increased. This disrupts the band of segregated particles at the interface and homogenized the joint zone. When the bonding time was increased to 30 minutes a corresponding increase was seen in grain size, resulting in more uniform distribution of micro- Al_2O_3 particles. In the reported studies on transient liquid phase diffusion bonding of Al-MMCs, it was shown that the width of the segregated zone at the joint center increased with increasing bonding time. The opposite of this relationship was seen when using the Ni- Al_2O_3 coating. As the bonding time increased, the width of the

segregated region decrease. This can be attributed to the heterogeneous nucleation of grains within the joint zone during solidification and this lead to grain refining at the joint. The high resolution SEM micrograph shown in Figure 33 revealed the presence of a nano- Al_2O_3 particle at the center of a grain. EDX spectra of the particle showed Al and O in high concentrations with traces of Mg. Comparing Gibbs free energy of formation at the bonding temperature for MgO (-1195 kJ/mol) and Al_2O_3 (-985 kJ/mol) it is found that Al_2O_3 is unstable in the presence of Mg hence it is like that some of the nano-size Al_2O_3 will decomposed to form MgAl_2O_4 compound.

The segregation of particles during isothermal solidification was accredited to the pushing of strengthening particles by the solidifying liquid-solid interface. Stefanescu [17, 18] showed that particle pushing can be assumed to be a steady-state condition under which the interface velocity can be assumed to be equal the rate of isothermal solidification This rate can be calculated using a model proposed by Sinclair [51]. The constant, ξ , signifies the solidification rate of the system. Increasing ξ results in faster solid-liquid interface motion, and a shorter duration of the isothermal solidification stage. The rate of isothermal solidification can be calculated using Equation 11.

$$\xi = -2(k - 1)^{-1} \sqrt{\frac{D}{\pi}} \cdot \frac{\exp\left(\frac{-\xi^2}{4D}\right)}{\text{erfc}\left(\frac{\xi}{2\sqrt{D}}\right)} \quad (11)$$

Where k is a partition coefficient given by $\frac{C_{La}}{C_{aL}}$ and D is the diffusivity of Ni into Al. The

diffusivity at 570°C is $4.69 \times 10^{-13} \text{ m}^2/\text{s}$, when the bonding temperature is increased to 620°C, the diffusivity also increased to $1.58 \times 10^{-12} \text{ m}^2/\text{s}$. This increase in diffusivity is reflected in a faster solid-liquid interface rate (ξ) and a shorter isothermal solidification stage.

The final concentration of Ni (C_{La}) was taken from the Al-Ni-Si phase diagram [30] to be 4.9 wt % for the bonding temperature of 620°C. The diffusivity of Ni in Al at 620°C is $D = 1.58 \times 10^{-12} \text{ m}^2/\text{s}$ [25, 31]. Using these values the predicted interface rate constant $\xi = -0.395 \mu\text{m/s}$ was calculated from Equation 8. This solidification rate is significantly less than the critical interface velocity (16 -400 $\mu\text{m/s}$) required to engulf dispersed particle during solidification [26]. Li et al. [21] suggested that particle segregation tendency is dependent on the relationship between the liquid film width produced at the bonding temperature, particle diameter and inter-particle spacing. When the liquid film width is large enough that sufficient particulate material is contained in the melt, particles will be pushed ahead of the solidifying liquid-solid interface resulting in particle segregation at the bond-line. However if the liquid film width is less than some critical value, segregation should not occur. WDS analysis across the joint zone as a function of bonding time indicated that the Ni volume at the joint center varied between 3.67 wt% after 1 minute and 0.15 vol.% after 30 minutes bonding time. The relationship between the width of segregated region and the maximum liquid width that formed during bonding was determined by using equation 12.

$$S_{sz} = W_{\max} \left[\frac{\delta_p + \chi_2}{\delta_p + \chi_1} \right] \quad (12)$$

Where δ_p is the average particle size, χ_1 is the inter-particle spacing in the as received MMC and χ_2 is the inter-particle spacing after bonding at the joint. By substituting $\delta_p = 28 \mu\text{m}$, $\chi_1 = 10 \mu\text{m}$ and $\chi_2 = 0$ into Equation 6.3, the relationship between the width of the particle segregated zone and the maximum width of the eutectic liquid phase was found to be, $S_{sz} = 0.74 W_{\max}$. This means that the width of the segregated zone is approximately 74% of the width of the maximum width of the eutectic liquid phase formed during bonding.

7. Conclusion

Transient liquid phase diffusion bonding of particle reinforced Al-6061 MMC using Ni-Al₂O₃ interlayer was successfully achieved using nano-composite Ni-Al₂O₃ coating. The results obtained from the spectroscopic analyses using WDS and XRD showed that Ni-Al₂O₃ coating the bonding process can be characterized in four distinct stages: interfacial contact and solid-state diffusion, which resulted in the formation of three reaction layers promoted by the diffusion of nickel into the aluminum base metal. The second stage of the joining process was the formation of an Al-Ni-Si eutectic liquid at the bonding temperature. It is supported that the reaction layers formed within the joint melted to form a liquid phase, followed by dissolution of the base metal (third stage) as the liquid spread between the bonding surfaces through capillary action. The final stage of bonding involved isothermal solidification at the bonding temperature in which the diffusion of Ni into Al results in a change in the composition of the liquid phase leading to solidification.

The joint shear strength was studied as a function of bonding parameters, bonding time, bonding temperature, interlayer thickness and interlayer particle size. The results showed that the joint shear strength increased with increasing bonding time, bonding temperature and interlayer thickness. On the other hand the results showed that bond strength increased when the interlayer particle size was reduced from 500 nm to 50 nm. The increase joint shear strength seen when Ni-Al₂O₃ coating were used was attributed to the presence of highly-dispersed nano-sized reinforcement particles in the joint region act to strengthen the joint region by Orowan bowing mechanism.

The results showed that an optimum joint strength of 144 MPa can be achieved if the following bonding parameters are used: 30 minutes bonding time, 620°C bonding temperature, and 11 μm thick Ni-Al₂O₃ coating. Within the parameter ranges tested the bonding pressure had the least effect on the joint shear strength of TLP bonded joints.

Author details

Kavian Cooke

Department of Mechanical Engineering, School of Engineering, University of Technology, Jamaica
